## List of Tables

Table 1. Table 1. State variables, covariates, and hyperparameters in the model. Page 6
Table 2. Data sources used for estimation. Page 19
Table3. Estimated values of process ( $\boldsymbol{\psi}_{\text {proc }}$ ) and observation ( $\boldsymbol{\psi}_{\boldsymbol{o b s}}$ ) hyperparameters. The values represent the mean from Bayesian samples, with $95 \%$ credible intervals within brackets. Parameters with single values were assumed as constants in the model. Page 21

Table 4. Estimates of instantaneous and annual mortality rates required to maintain a constant harvest of maximum sustainable yield when biomass levels are $\geq B_{\text {MsY }}$. $B_{\text {MSY }}$ and $F_{\text {MSY }}$ from Zhao and Lester (2013) and described in Rowe et al. (2013). Page 30

Table 5. Candidate list of recreational angling regulations for Lake Nipissing Walleye. Page 33

Table 6. Biological indicators and risk criteria. Page 38
Table 7. Performance indicators and risk criteria for 11 possible angling regulation simulations 5 years after implementation. Page 63

## List of Figures

Figure 1. Schedule of the main events and population processes in the model. Each year y starts on January $1^{\text {st }}$ and ends on December $31^{\text {st. }}$. Catch" represents the occurrence of a FWIN survey, typically in the Fall, and "Spawning" represents spawning events that typically occur in the Spring. "Reproduction" represents the production of eggs by adults whose size and abundance were assessed in the previous Fall (during a Catch event). "Recruitment" represents the survivorship from egg (Spawning) to the next FWIN event (Catch). For the first year (1998), only "Growth" was included as a process because growth parameters were assumed to be constant, whereas mortality and recruitment varied annually. Estimating mortality and recruitment for 1998 would require an independent estimate of initial abundance in 1997, which was not possible (the FWIN program on Lake Nipissing was started in 1998. Page 3

Figure 2. Bayesian network for the Walleye population state-space model, showing how variables and parameters are related through conditional probabilities. The large rectangle comprehends time-varying (dynamical) variables. Subscripts in each variable represent sampling year ( $y=1$, $2,3, \ldots, Y$ ). Ellipses represent random variables (or parameters); squares represent factors assumed to be fixed at a constant value. Gray filling represents directly observed (sampled) data, whereas white filling represents unobserved (latent) variables whose values are estimated. Arrows represent relationships, i.e., the distribution of the random variable the arrow is pointing at is conditional on the values of the variable the arrow is pointing from. $\mathbf{X}_{\mathrm{y}}$ is the set of environmental covariates observed in year ' $y$ '; in the current model version, only the annual growing degree-days above $5^{\circ} \mathrm{C}$ (GDD5) was used. $\mathbf{N}_{\mathrm{y}}$ is the set of population states in year 'y' that include: (i) abundance per age class, (ii) mean size (total length) per age class, (iii) mortality rate (year ${ }^{-1}$ ) per age class, and (iv) carrying capacity of Age-0 recruits. $\mathbf{C}_{y}$ is the set of variables observed in the FWIN catch that year, including: (i) number of fish caught per age class, and (ii) lengths of all fish caught. $\mathrm{E}_{\mathrm{y}}$ is sampling effort (number of nets) used that year. $\psi_{\text {proc }}$ is the set of hyperparameters determining population processes in the model, i.e., the transition between population state variables. $\psi_{\text {obs }}$ is the set of hyperparameters determining observation (catch), i.e., the transition from population states to observed variables in the catch. The hyperparameters also influence observed variables that are important to infer on population processes ( $\mathbf{V}_{\text {proc }}$ ) or observation ( $\mathbf{V}_{\text {obs }}$ ), but whose temporal structure was ignored for simplicity. They are referred to as auxiliary variables. $\mathbf{V}_{\text {proc }}$ is the set of auxiliary variables representing the reproductive state of the population, including (i) the maturity state (mature female versus other) of all fish caught, and (iv) the gonad-somatic index (GSI) of females caught during Spring at Wasi Falls on a subset of years. $\mathbf{V}_{\text {obs }}$ is the set of fish total length and gillnet mesh size variables, including only individuals containing information for both and used to inform on gillnet selectivity. Page 5

Figure 3. Bayesian network for the process sub-model, exemplifying a three-year period (assuming hypothetically that the third year is the last year). Annually variable population states and covariate (growing degree-days, GDD5) are contained within the major rectangle, and their subscripts indicate the year. The other variables are either (i) hyperparameters (white filled ellipses represent random variables and rectangles represent fixed parameters, i.e., estimated separately or imposed as constants in the model) or (ii) observed auxiliary variables (sampled gonad-somatic indices at the spawning site, $\mathbf{g}$; and maturity states from the FWIN catches, $\boldsymbol{\phi}$ ). Dashed arrows represent deterministic relationships, continuous arrows represent stochastic relationships (each arrow starts with a black dot, to facilitate identifying the conditioning variable they are pointing from versus the conditioned variable they are pointing to). Symbols marked in bold represent vectors. Initial lengths $\left(\boldsymbol{\lambda}_{0}\right)$ were based on year 0 , whereas initial abundances $\left(\mathbf{n}_{1}\right)$ and adult mortality $\left(z_{3+, 1}\right)$ were based on year 1 as both varied annually and required the existence of catch data to not be confounded. For a full list of symbols and definitions, see Table 1. Page 13

Figure 4. Bayesian graph for the observation sub-model, exemplifying a two-year period. Annually variable population states and covariate (sampling effort $E$, number of nets) are contained within the major rectangle, and their subscripts 1 or 2 indicate the year. The other variables are either (i) hyperparameters (white filled ellipses represent random variables and rectangles represent fixed parameters, i.e., estimated separately or imposed as constants in the model) or (ii) observed auxiliary variables. Arrows represent stochastic relationships between variables (each arrow starts with a black dot, to facilitate identifying the conditioning variable they are pointing from versus the conditioned variable they are pointing to). Symbols marked in bold represent vectors. For a full list of symbols and definitions, see Table 1. Page 16

Figure 5. Effect of the encounter-contact exponent ( $\beta$ ) on catchability curves (A) and mortalities (B). In $(A)$, solid lines are mean curves from Bayesian samples, and the gray area is their combined $95 \%$ credible interval. All curves cross at the same coordinate ( $475 \mathrm{~mm}, 1.04$ ha• $^{-1}$ net $^{-1}$ ), which is the mean length and catchability from the calibration lake dataset with a relative effort of 0.0335 nets $\bullet h^{-1}$. In (B), the mean and $95 \%$ credible intervals of Age 0 to 2 mortality rate ( $z_{2-}$, year ${ }^{-1}$ ) shows a linear relationship with $\beta$. Page 21

Figure 6. Predicted versus observed catches across years for ages 0 to 11. Red dotted lines represent observations; thin black lines and gray areas represent predictions (median and 95\% credible intervals, respectively). Page 23

Figure 7. Length-at-age distributions for cohorts born from 1993 to 2016 (birth year at the top of each graph; figure continues in the next two pages). Histograms (gray bars) are empirical probability density distributions of observed catch, and black curves represent the mean predicted size distributions (after adjusting for catch probabilities). Page 24

Figure 8. Reproductive parameters. (A) distribution of gonad-somatic index from the Bayesian samples, with the mean ( 0.168 ) marked by the vertical line. $(B)$ the probability of being a mature female in the Walleye population as a function of length (red line and gray band are mean the mean curve and $95 \%$ credible interval, black dots are observed data). (C) mean fecundity per fish as a function of length (red line and gray band are mean the mean curve and 95\% credible interval). Page 26

Figure 9. Annual variation in adult mortality (A), maximum recruitment (B), mean length of recruits (C), age-specific abundances ( $D$, ages vary from 0 in the background to $12+$ in the foreground)), biomass of fish larger or equal to $350 \mathrm{~mm}(E)$, and the mean length of fish in the population (F). Page 27

Figure 10. Estimated relationship between Growing-Degree Days (GDD5) and maximum recruitment (A, in a log-scale) and mean length of recruits (B). The black line represents the regression with mean parameter values, and gray lines are regressions from individual Bayesian samples. Red dots and whiskers are the mean and $95 \%$ credible interval for each year. Page 27

Figure 11. Stock-recruitment relationships. Each curve represents the geometric mean for a year, which goes from 1999 to 2016, based on the estimates of maximum recruitment. Red dots are the geometric means of the total number of eggs produced by adults in a given year (x-axis) and total number of surviving recruits the next year ( $y$-axis). Gray dots are individual estimates from the Bayesian samples. In (A), the x-axis is expanded to show the position of point estimates with respect to the ascending part of the curves; in (B) the $x$-axis range is restricted to the region containing the point estimates and to show more clearly the relationship between total number of eggs (an index of stock size) and surviving recruits. Page 28

Figure 12. Schematic diagram showing the general harvest control model for managing Walleye on Lake Nipissing, including reference points (1 and 2) and conceptual harvest removal rates (dashed line, 3). Adapted from the Lake Nipissing Walleye Risk Assessment Model for Joint Adaptive Management ('RAMJAM' - in Rowe et al. 2013, page 2). Note: The Biomass index (x-axis) = FWIN Biomass Estimate $\bullet$ Biomass-at-MSY ${ }^{-1}$ and Mortality index ( $y$-axis) $=$ FWIN $Z_{350} \bullet Z_{\text {MSY }}{ }^{-1}$. Page 29

Figure 13. Schematic diagram showing the proposed harvest control model for managing Walleye on Lake Nipissing, including reference points (1 to 4) and conceptual harvest removal rates (dashed line, 5). Note: The Biomass index (x-axis) = FWIN Biomass Estimate•Biomass-at-MSY ${ }^{-1}$ and Mortality index (y-axis) $=$ FWIN $Z_{350} \bullet Z_{M_{M Y}}{ }^{-1}$. Page 30

Figure 14. Proposed harvest control rules and Walleye stock status trajectory based on the 1998 to 2018 FWIN fisheries-independent data (boxes joined by blue line). The 2015 to 2018 data points (filled blue boxes) are the years when further restrictions were applied to both the angling and commercial fisheries. Note: The Biomass index (x-axis) = FWIN Biomass Estimate $\bullet$ Biomass-at-MSY ${ }^{-1}$ and Mortality index (y-axis) $=\mathrm{FWIN}_{350} \bullet \mathrm{Z}_{\mathrm{MSY}}{ }^{-1}$. Page 31

Figure 15. Function used to convert harvest ratios simulated from the creel data ( $x$-axis) into a multiplier of angling mortalities, which in turn are used to calculate new total mortalities according to Equation (2). The function is plotted as the thick curve. The dashed lines mark the coordinates ( 1,1 ) and ( $8.5,2.53$ ) as specified by criteria (ii) and (iii) above; and the thin diagonal line is the 1:1 line. Page 36

Figure 16. Young-of-year (Age-0) recruitment from Bayesian model (estimate and 95\% credible interval) from 1999 to 2016. Page 37

Figure 17. Cumulative probability of reaching the management recovery target biomass ( $1.3 \mathrm{~B}_{\text {mš }}$ ) under either low or high recruitment. The probabilities were calculated from the predictive Bayesian distribution assuming low recruitment (using MCMC values from 1999 to 2009) or high recruitment (using MCMC values from 2010 to 2016) (Figure 16). ## Executive Summary

This report is a direct response to the Lake Nipissing management plan timeline for a review after 5 years and further builds upon the recommendations of the third-party Quantitative Fisheries Centre report. Using the Fall Walley Index Netting time series (starting in 1998) a Bayesian state-space model has been developed to assist with future management discussions. Besides the structural differences between the current Risk Assessment Model for Joint Adaptive Management and Bayesian model the most important change was not to incorporate the harvest data, from either the angling or commercial fisheries, in the present model version. This change was made to address the concern that the cost and feasibility of maintaining the collection of fisheries-dependent information (i.e., winter and open water angler creel surveys, and commercial catch monitoring) may not be sustainable on an annual basis into the future. The results from the Bayesian model have shown that the current management system should allow the Lake Nipissing Walleye population to reach its desired biomass recovery target in the near future. The simulated effects of a variety of alternate recreational angling rules were compared and there appear to be several options that can greatly decrease the risk to the resource while maintaining or increasing harvest into the near future. The model requires the annual data collected from the Fall Walley Index Netting program on Lake Nipissing (at least until the Walleye population has reached the recovery target of $1.3 \mathrm{~B}_{\mathrm{MSY}}$ ).

## Résumé

Ce rapport est une réponse directe à l'échéancier du plan de gestion des pêches du lac Nipissing, qui prévoit un examen au bout de cinq ans. Il s'appuie sur les recommandations du rapport de l'organisme tiers Quantitative Fisheries Center. À partir des séries issues du décompte automnal de prises de dorés jaunes au filet (en place depuis 1998), un modèle d'espaces d'états bayésien a été mis au point pour alimenter les discussions futures en matière de gestion. Outre les différences structurelles entre le modèle actuel d'évaluation des risques applicable à la gestion adaptative conjointe et le modèle bayésien, le principal changement était de ne pas intégrer de données sur la récolte, qu'il s'agisse de pêche à la ligne ou de pêches commerciales, à la version actuelle du modèle. Ce changement a été apporté en réponse à la préoccupation selon laquelle le coût et la faisabilité du maintien de la collecte de données tributaires des pêches (c.-à-d. des enquêtes par interrogation des pêcheurs en eaux libres et d'hiver et la surveillance des prises commerciales) pourraient à l'avenir ne pas être viables selon un cycle annuel. Les résultats extraits du modèle bayésien ont montré que le système de gestion actuel devrait permettre à la population de dorés jaunes du lac Nipissing d'atteindre sa cible de rétablissement de la biomasse souhaitée dans un avenir proche. Les effets simulés de diverses autres règles pouvant être appliquées à la pêche récréative ont été comparés, et il semble qu'il y ait plusieurs options pouvant réduire grandement le risque pesant sur la ressource tout en maintenant ou augmentant la récolte dans un avenir proche. Le modèle nécessite les données annuelles collectées dans le cadre du programme de décompte automnal de prises de dorés jaunes au filet dans le lac Nipissing (au moins jusqu'à ce que la population de dorés jaunes ait atteint sa cible de rétablissement, à savoir une biomasse correspondant au rendement maximal durable de 1,3 ).

# Lake Nipissing Walleye - Bayesian Model and Harvest Control Rules 

## 1 - Introduction

Sustainable fisheries management is an adaptive process that relies on sound science, innovative management approaches, effective enforcement, meaningful partnerships, and robust public participation. Sustainable fisheries play an important role in Ontario's economy by providing opportunities for recreational, commercial, and subsistence fishing. Lake Nipissing Walleye (Sander vitreus (Mitchill, 1818)) support harvest-oriented fisheries that are of exceptional recreational, subsistence, and commercial importance in northeastern Ontario with complex management and distinct challenges. As a highly exploited fishery subject to multiple forms of fishing mortality, several attempts have been made to develop stock-recruitment relationships for this species to inform management policies (Zhao and Lester 2013, Rowe et al. 2013). Under the current management plan, biologists and resource managers already track changes in population numbers, size, growth, and mortality (OMNRF 2014). The current Walleye management system on Lake Nipissing uses a limit reference point method to manage harvest alongside population biomass estimates (Rowe et al. 2013). There is a need to implement evidence-based management, where scientific evidence from monitoring and research is used to inform more robust and transparent management decisions. Monitoring, evaluation, and reporting are critical stages of evidence-based management, which focus on assessing environmental state and pressures, evaluating management effectiveness, publicly reporting findings, demonstrating public accountability, and delivering the evidence-base to inform adaptive management.

The angling and commercial fisheries on Lake Nipissing are both defined as open access. Open access is the condition where access to the fishery (for the purpose of harvesting fish) is unrestricted (i.e., the right to catch fish is free and open to all). The angling fishery has limited regulation of effort (season timing and duration) and is managed using length- and creel-based restrictions while the commercial fishery has direct control of effort (through season, gear restrictions, and harvest termination - closing the fisheries and cancellation of fishing permits - once the quantity of Walleye specified in the annual Nipissing First Nation Fisheries Law is reached). Subsistence fishing is defined under the Nipissing First Nation Fisheries Law as "an NFN member fishing with one panel of net, or if subsistence fishing with more than one panel of net, the member is registered with the NFN Natural Resources Department. This may also include other fishing activity including but not limited to angling or spear fishing" (Nipissing First Nation 2019).

Annual estimates of the number and weight of Walleye harvested are derived from creel surveys (performed by Ontario Ministry of Natural Resources and Forestry (OMNRF) staff during both the winter and open water angling seasons) and harvest monitoring (with mandatory daily catch reporting by permitted fishers and catch sampling by Nipissing First Nation (NFN) Natural Resources Department staff) of the commercial fishery (fisheries-dependent data). The extent of the subsistence fishery and the amount harvested is unknown. Annual Fall Walleye Index Netting (FWIN) have been cooperatively performed annually since 1998 by OMNRF and NFN to provide fisheries-independent data on various life history parameters (e.g., length, weight, sex determination, maturity, and tissues collected for age interpretation) and biomass of Walleye $\geq 350 \mathrm{~mm}$ total length. The current management model - Lake Nipissing Walleye Risk Assessment Model for Joint Adaptive Management (i.e., the RAMJAM model) -
uses the data from both the fisheries-dependent and fisheries-independent sources to set annual safe harvest ceilings (Rowe et al. 2013).

In the 2014 Lake Nipissing management plan the OMNRF committed to review the RAMJAM model after 5 years (OMNRF 2014). Moreover, an external third-party review conducted by the Quantitative Fisheries Center (QFC) suggested that the current RAMJAM model was unnecessarily complex, relied upon questionable (and sometimes difficult to assess) assumptions and may not be implementable as detailed in the RAMJAM report (Jones et al. 2016). The panel believed the most pressing task was to create an age-structured stock assessment model using FWIN data.

This report is a direct response to the Lake Nipissing management plan timeline for a review after 5 years and further builds upon the recommendations of the third-party QFC report. Using the FWIN time series (starting in 1998) a Bayesian state-space model has been developed to assist with future management discussions. Besides the structural differences between the RAMJAM and Bayesian models the most important change was not to incorporate the harvest data, from either the angling or commercial fisheries, in the present model version. This change was made to address the concern that the cost and feasibility of maintaining the collection of fisheries-dependent information (i.e., winter and open water angler creel surveys, and commercial catch monitoring) may not be sustainable on an annual basis into the future. The results from the Bayesian model have been used to:

- modify the current harvest control rule,
- evaluate the effectiveness of the current management efforts (i.e., the 460 mm minimum size limit with 2 fish daily creel limit for the winter and open water angling fisheries, and the measures stipulated in the Nipissing First Nation Fisheries Laws),
- simulate the effects of a suite of 11 possible angling regulations, and
- propose future monitoring needs to assess the status of the Lake Nipissing Walleye population

## 2 - Model Description

## 2.1 - Model objectives

The model has four main objectives:
(i) to estimate Walleye population structure and demographic parameters from the Fall Walleye Index Netting (FWIN) surveys on Lake Nipissing,
(ii) to assess the importance of stock size versus environmental drivers on Walleye recruitment,
(iii) to simulate population dynamics and its response to fisheries regulation scenarios, and
(iv) to estimate parameter uncertainty and account for it when making population projections.

## 2.2 - Model overview

## This section of the report provides and overview of the model structure. More detailed descriptions of its variables, parameters, and their relationships are provided in Sections 2.3 and 2.4.

The Bayesian state-space model is an age- and size-structured model of Lake Nipissing Walleye population dynamics. It is also data-driven, as the processes and state variables reflect the structure and availability of data from the FWIN monitoring protocol (Morgan 2002). FWIN surveys have been carried out on Lake Nipissing annually since 1998. The main annual fisheries assessment (FWIN) occurs during the fall, usually in October. The catch from the FWIN provides information on fish age, size, sex, and maturity state, which help to infer the true state of the population at that time. An important annual event is spawning, which for Walleye typically occurs during the spring (Figure 1). Reproduction is dependent on the size (length) and number of potential spawners, and because these two variables are only assessed during the preceding fall, annual mortality and growth are assumed to be concentrated between Spawning and Catch events (Figure 1). From the total number of produced eggs, only a fraction will survive to become Age-0 recruits the next fall. The survivorship from eggs and recruits is determined by an annually variable recruitment carrying capacity which encapsulates all density-dependence in the model (Andersen et al. 2016). Although spawning data were not assessed on an annual basis, auxiliary data from the Wasi Falls spawning site sampled during a subset of years could be used to infer on reproductive traits of Walleye, such as gonad production and absolute fecundity as a function of fish length.

Figure 1. Schedule of the main events and population processes in the model. Each year y starts on January $1^{\text {st }}$ and ends on December $31^{\text {st }}$. "Catch" represents the occurrence of a FWIN survey, typically in the Fall, and "Spawning" represents spawning events that typically occur in the Spring. "Reproduction" represents the production of eggs by adults whose size and abundance were assessed in the previous Fall (during a Catch event). "Recruitment" represents the survivorship from egg (Spawning) to the next FWIN event (Catch). For the first year (1998), only "Growth" was included as a process because growth parameters were assumed to be constant, whereas mortality and recruitment varied annually. Estimating mortality and recruitment for 1998 would require an independent estimate of initial abundance in 1997, which was not possible (the FWIN program on Lake Nipissing was started in 1998).

The model represents the catch from the FWIN surveys explicitly as a stochastic phenomenon resulting from underlying (latent) population states (Newman et al. 2014). This is formally represented in Figure 2. The connection between population state and the observed data (i.e., the transition from $\mathbf{N}$ to $\mathbf{C}$ in Figure 2) is given by an observation sub-model, which specifies how gillnet catchability, selectivity, sampling effort, and observation error translate abundances and size distributions into expected
catches. Changes between states, which make up population dynamics, are also stochastic and are determined in-part by a process sub-model (i.e., the transition from $\mathbf{N}_{\mathrm{y}}$ to $\mathbf{N}_{\mathrm{y}+1}$ ). This means that the quantities of interest - abundance, biomass, age and size structure, mortality, and recruitment - are explicitly represented as unobserved variables in an age-structured population model. They are estimated only indirectly through their connection with the observed variables. The model also includes auxiliary variables (represented by $\mathbf{V}_{\text {proc }}$ and $\mathbf{V}_{\text {obs }}$ in Figure 2), which comprise variables such as observed maturity states or captured length-at-each-mesh-size. Even though these variables were recorded as part of the annual catches, they were assumed to be constant, and as such, the lack of temporal dynamics is what distinguishes them from other variables. They do not affect any other variable in the model but are affected by process or observation parameters, and therefore are important to make inferences on these parameter values.

One advantage of this multi-level representation is that it can impose more realistic constraints on the population states, for instance by forcing the expected abundance of a cohort to only decrease with time. Additionally, this formulation allows the propagation of uncertainty around all population state variables and parameters, as well as accounting for their correlation structure. This is important if the model is to be used for predicting the variability in population dynamics arising from parameter uncertainty, which in turn can be used to estimate probabilities of any given state being above or below certain threshold - the probability of achieving a stated objective (e.g., the probability that adult biomass will be above a hypothetical management target in a given year).

Figure 2. Bayesian network for the Walleye population state-space model, showing how variables and parameters are related through conditional probabilities. The large rectangle comprehends time-varying (dynamical) variables. Subscripts in each variable represent sampling year ( $y=1,2,3, \ldots, Y$ ). Ellipses represent random variables (or parameters); squares represent factors assumed to be fixed at a constant value. Gray filling represents directly observed (sampled) data, whereas white filling represents unobserved (latent) variables whose values are estimated. Arrows represent relationships, i.e., the distribution of the random variable the arrow is pointing at is conditional on the values of the variable the arrow is pointing from. $\mathbf{X}_{\mathrm{y}}$ is the set of environmental covariates observed in year ' $y$ '; in the current model version, only the annual growing degree-days above $5^{\circ} \mathrm{C}$ (GDD5) was used. $\mathbf{N}_{y}$ is the set of population states in year ' $y$ ' that include: (i) abundance per age class, (ii) mean size (total length) per age class, (iii) mortality rate (year ${ }^{-1}$ ) per age class, and (iv) carrying capacity of Age-0 recruits. $\mathbf{C}_{\mathrm{y}}$ is the set of variables observed in the FWIN catch that year, including: (i) number of fish caught per age class, and (ii) lengths of all fish caught. Ey is sampling effort (number of nets) used that year. $\psi_{\text {proc }}$ is the set of hyperparameters determining population processes in the model, i.e., the transition between population state variables. $\psi_{o b s}$ is the set of hyperparameters determining observation (catch), i.e., the transition from population states to observed variables in the catch. The hyperparameters also influence observed variables that are important to infer on population processes ( $\mathbf{V}_{\text {proc }}$ ) or observation ( $\mathbf{V}_{\text {obs }}$ ), but whose temporal structure was ignored for simplicity. They are referred to as auxiliary variables. $\mathbf{V}_{\text {proc }}$ is the set of auxiliary variables representing the reproductive state of the population, including (i) the maturity state (mature female versus other) of all fish caught, and (iv) the gonad-somatic index (GSI) of females caught during Spring at Wasi Falls on a subset of years. $\mathbf{V}_{\text {obs }}$ is the set of fish total length and gillnet mesh size variables, including only individuals containing information for both and used to inform on gillnet selectivity.

The process and observation sub-models are formulated as equations whose shape and magnitude are determined by the so-called hyperparameters ( $\psi_{\text {proc }}$ and $\psi_{\text {obs }}$, Figure 2 ), which are random variables whose values are not conditional on any other variable. For instance, in the process sub-model, the number of

Age-0 Walleye recruits surviving from spawning to the time of a FWIN survey is constrained by a carrying capacity (i.e., the maximum of the stock-recruitment relationship for a given year, Rmax). The expected value of this carrying capacity ( $\mu_{R \max }$ ) is modelled in a logarithmic scale and is assumed to follow a linear relationship with the annual growing degree-days above $5^{\circ} \mathrm{C}$ (GDD5). The expected value for the carrying capacity and the realized carrying capacity represent two hierarchical levels of a population state (member of $\mathbf{N}$ ), GDD5 is an environmental covariate (member of $\mathbf{X}$ ), whereas the intercept and slope of the linear relationship with GDD5 are process hyperparameters (members of $\psi_{\text {proc }}$ ). In the observation sub-model, one example is the function relating fish length to the encounter-contact rate with the gillnet, which is assumed to follow a power law $\propto$ length ${ }^{\beta}$. The distribution of fish lengths is another population state, then a member of $\mathbf{N}$, whereas the encounter rate exponent $\beta$ - which determines how rapidly encounter rate with the FWIN nets increases with length - is an observation hyperparameter (member of $\psi_{\text {obs }}$ ). Together, they help determining the chances of gillnets catching any specific group of fish lengths in a given year, represented by the vector $\mathbf{l}_{y}$, which is a member of $\mathbf{C}$ (Table 1).

In summary, to get to the observed variables from the FWIN catch in a given year, there is a chain of conditional probabilities from the most basic parameters and variables through a series of intermediate latent variables (e.g., carrying capacity of recruits, population length distribution). This also serves to point out that Figure 2, by aggregating several population states or observed variables into a single major category, is just a higher-level and low-resolution simplification. The details of all process and observation variables and functions will be described in the following sections. The full list of process and observation variables and hyperparameters, which helps to outline their hierarchical structure, is presented in Table 1.

Table 1. State variables, covariates, and hyperparameters in the model

| Symbol | Description |
| :--- | :--- |
| State variables |  |
| $\mathbf{N}_{y}$ | Set of population state variables in year $y$ |
| $\mathbf{n}_{y}$ | Vector of population abundances (number of fish per age class) in year $y$ |
| $n_{a, y}$ | Abundance (number of fish) of age class $a$ in year $y$ |
| $\mathbf{z}_{y}$ | Vector of mortality rates (year ${ }^{-1}$ ) per age class in year $y$ |
| $z_{a, y}$ | Mortality rate $\left(\right.$ year $\left.^{-1}\right)$ of age class $a$ in year $y$ |
| $z_{2-}$ | Mortality rate $\left(\right.$ year $\left.^{-1}\right)$ of 2-year old or younger fish, i.e., for $a \leq 2$ |
| $z_{3+, y}$ | Mortality rate (year ${ }^{-1}$ ) of 3-year old or older fish, i.e., for $\left.a \geq 3\right]$ in year $y$ |
| $S_{a, y}$ | Survival probability from age $a$ to age $a+1$, from year $y$ to year $y+1$ |
| $F_{a, y}$ | Absolute fecundity of a mature female fish aged $a$ in year $y$ |
| $\rho_{a, y}$ | Probability of fish aged $a$ in year $y$ being a mature female |
| $O_{a, y}$ | Mean fecundity of fish aged $a$ in year $y$ |
| $R_{a, y}$ | Realized number of age-0 recruits produced per fish aged $a$ in year $y$ |
| $R m a x_{y}$ | Maximum total number (carrying capacity) of Age-0 recruits in year $y$ |

| $\mu_{R m a x y}$ | Expected (mean) value of $\log _{10}\left(R m a x_{y}\right)$ |
| :--- | :--- |
| $\boldsymbol{\lambda}_{y}$ | Vector of mean total length (mm) per age class in year $y$ |
| $\lambda_{0, y}$ | Mean total length (mm) of age-0 recruits in year $y$ |
| $\mu_{\lambda_{0, y}}$ | Expected (mean) value of $\lambda_{0, y}$ |
| $\lambda_{a, y}$ | Mean total length (mm) of fish aged $a$ in year $y$ |
| $\mathbf{C}_{y}$ | Set of FWIN catch variables in year $y$ |
| $\mathbf{c}_{y}$ | Vector of catches (number of fish caught per age class) in year $y$ |
| $c_{a, y}$ | Number of fish aged $a$ caught in year $y$ |
| $\mathbf{l}_{y}$ | Set of vectors of total lengths (mm) of fish caught in year $y$ |
| $\mathbf{l}_{a, y}$ | Vector of total lengths (mm) of fish aged $a$ caught in year $y$ |
| $l_{a, y, i}$ | Total length of individual fish $i$ aged $a$ and caught in year $y$ |
| $\mathbf{V}$ | Set of auxiliary variables |
| $\mathbf{V}_{p r o c}$ | Set of auxiliary process variables |
| $\boldsymbol{\phi}$ | Vector of maturity states |
| $\phi_{a, y, i}$ | Maturity state of fish $i$ aged $a$ and caught in year $y$ ( $\phi_{a, y, i}=1$ if mature female, 0 otherwise) |
| $\mathbf{g}$ | Vector of gonad-somatic indices from Wasi Falls spawning sample |
| $\mathrm{g}_{i}$ | Gonad somatic index of individual $i$ from Wasi Falls spawning sample |
| $\mathbf{V}_{o b s}$ | Set of auxiliary observation variables |
| $\mathbf{l}_{m e s h}$ | Vector of total lengths from mesh-specific samples |
| $l_{m e s h, i}$ | Total length (mm) of individual fish $i$ from mesh-specific samples |
| $\mathbf{m}_{m e s h}$ | Vector of mesh sizes from mesh-specific samples <br> $m_{m e s h, i}$ |
| Mesh size (mm) of gillnet panel where individual fish $i$ was caught |  |

Covariates
$\mathbf{X}_{y} \quad$ Set of environmental covariates
$G D D 5_{y} \quad$ Growing degree-days above $5^{\circ} \mathrm{C}$ of year $y$
$E_{y} \quad$ Sampling effort (number of nets) in year $y$
Process hyperparameters ( $\boldsymbol{\psi}_{\text {proc }}$ )

| $A_{R \max }$ | Intercept of maximum recruitment-GDD5 relationship |
| :--- | :--- |
| $B_{R \max }$ | Slope of maximum recruitment-GDD5 relationship |
| $\sigma_{R \max }$ | Standard deviation of maximum recruitment-GDD5 relationship |
| $A_{\lambda_{0}}$ | Intercept of recruit mean length-GDD5 relationship |
| $B_{\lambda_{0}}$ | Slope of recruit mean length-GDD5 relationship |
| $\sigma_{\lambda_{0}}$ | Standard deviation of recruit mean length-GDD5 relationship |
| $\rho \max$ | Maximum probability of being a mature female |
| $\theta$ | Steepness of the maturation curve |
| $\lambda_{50 \%}$ | Mean size at 50\% probability of maturation (mm) |
| $g$ | Mean gonad somatic index |
| $\sigma_{g}$ | Standard deviation of gonad somatic index |
| $\lambda_{\infty}$ | Asymptotic body size (mm) |
| $k$ | von Bertalanffy growth coefficient (year ${ }^{-1}$ ) |
| $z_{2-}$ | Mortality rate of age-0 to age-2 fish (year ${ }^{-1}$ ) |
| $\sigma_{z_{3+}}$ | Standard deviation around annual mortality rate of Age 3+ fish |
| $z_{3+, 1}$ | Initial mortality rate of age 3 and older fish (year ${ }^{-1}$ ) |

| $\epsilon$ | Egg size $(\mathrm{g})$ |
| :--- | :--- |
| $\omega$ | Coefficient of weight-length relationship |
| $b$ | Exponent of weight-length relationship |
| $\mathbf{n}_{1}$ | Vector of initial age distribution of abundances ( $\log _{10}$ scale) |
| $n_{a, 1}$ | Initial abundance of age $a$ fish (log 10 scale) |
| $\boldsymbol{\lambda}_{0}$ | Vector of initial age distribution of mean lengths (mm) |
| $\lambda_{a, 0}$ | Initial mean length of age $a$ fish (mm) |
| Observation hyperparameters ( $\boldsymbol{\psi}_{o b s}$ ) |  |
| $\delta$ | Dispersion factor for the number of fish caught |
| $\sigma_{l}$ | Dispersion factor for individual length distribution |
| $\mu_{r}$ | Position factor for retention rate |
| $\sigma_{r}$ | Dispersion factor for retention rate |
| $\alpha$ | Coefficient determining individual probability of catch |
| $\beta$ | Exponent relating length to probability of catch |

## 2.3 - Process sub-model

The process sub-model contains a mix of deterministic and stochastic relationships between variables (Figure 3). The deterministic processes mostly comprehend the transition of population abundance and size distribution from one year to another, for given mortality and growth parameters. The stochastic processes are constrained to: (i) recruitment, determining the number and length of Age-0 fish during the fall, (ii) adult mortality, which varies annually, and (iii) reproductive traits, such as maturity and gonad production (both used as auxiliary variables).

### 2.3.1 - Deterministic processes

The basic information comprising the population state in year $y$ is given by the vectors of abundance $\mathbf{n}_{y}$, mortality $\mathbf{z}_{y}$, and mean length $\boldsymbol{\lambda}_{y}$, represented in Figure 2 as the set $\mathbf{N}_{\mathrm{y}}$ :
$\mathbf{N}_{y}=\left\{\mathbf{n}_{y}, \mathbf{z}_{y}, \lambda_{y}\right\}$
The abundance vector is a column vector $\mathbf{n}_{y}=\left[n_{0, y}, n_{1, y}, n_{2, y}, \ldots, n_{12+, y}\right]^{\mathrm{T}}$ (where T means the transpose operation), whose elements $n_{a, y}$ give the abundance of fish of age $a$ in year $y$. The last age class $12+$ include all fish 12 years old or older and was chosen as a compromise between the range of ages necessary to properly inform demographic processes and the availability of fish in the catch.
Similarly, the mortality vector $\mathbf{z}_{y}=\left[z_{0, y}, z_{1, y}, z_{2, y}, \ldots, z_{12+, y}\right]^{\mathrm{T}}$ and the mean length vector $\lambda_{y}=$ $\left[\lambda_{0, y}, \lambda_{1, y}, \lambda_{2, y}, \ldots, \lambda_{12+, y}\right]^{\mathrm{T}}$ contain age- and year- specific mortality rates (year ${ }^{-1}$ ) and mean total lengths ( mm ). Here the use of the Greek letter $\lambda$ to represent unobserved (latent) mean lengths, in contrast to observed lengths, which are represented by l(Section 2.4).

Mortality rates, when integrated over the course of a year, give the probabilities of survival:
$s_{a, y}=e^{-z_{a, y}}$
which determine the change in abundance within a cohort from one year to the next:
$n_{a+1, y+1}=s_{a, y} n_{a, y}$
The total number of Age-0 recruits in year $y+1$ is equal to the sum of recruits ( $R_{a, y+1}$ ) produced by each fish that had age $a$ in the previous fall multiplied by their abundance ( $n_{a, y}$ ):
$n_{0, y+1}=\sum_{a} R_{a, y+1} n_{a, y}$
The transition between abundances in year $y$ to year $y+1$ can be represented in a more compact way using matrix multiplication:
$\mathbf{n}_{y+1}=\mathbf{M}_{y} \mathbf{n}_{y}$
where $\mathbf{n}_{y}$ is the abundance vector as defined above, and $\mathbf{M}_{y}$ is a population transition matrix containing survivorships and recruitment terms:

$$
\mathbf{M}_{y}=\left[\begin{array}{ccccccc}
R_{0, y+1} & R_{1, y+1} & R_{2, y+1} & R_{3, y+1} & \cdots & R_{11, y+1} & R_{12+, y+1}  \tag{6}\\
s_{0, y} & 0 & 0 & 0 & \cdots & 0 & 0 \\
0 & s_{1, y} & 0 & 0 & \cdots & 0 & 0 \\
0 & 0 & s_{2, y} & 0 & \cdots & 0 & 0 \\
\vdots & \vdots & \vdots & \vdots & \ddots & \vdots & \vdots \\
0 & 0 & 0 & 0 & \cdots & 0 & 0 \\
0 & 0 & 0 & 0 & \cdots & s_{11, y} & s_{12+, y}
\end{array}\right]
$$

The recruitment term $R_{a, y+1}$ in turn depends on: (i) the mean number of eggs (or mean fecundity) produced by each fish that were aged $a$ in the previous Fall ( $O_{a, y}$ ) (i.e., the transition marked as "Reproduction" in Figure 1), and (ii) an implicit mortality that occurs between spawning in spring and the time of population assessment in the following Fall ("Recruitment" in Figure 1). This egg to age$0 /$ juvenile mortality is assumed as the only source of density dependence in the model, and is represented by a Beverton-Holt stock-recruitment relationship (Andersen et al. 2016):
$R_{a, y+1}=\frac{\operatorname{Rmax}_{y+1} O_{a, y}}{\operatorname{Rmax}_{y+1}+\sum_{a}\left(n_{a, y} O_{a, y}\right)}$
where $\operatorname{Rmax}_{y+1}$ is the maximum total number, or carrying capacity, of Age-0 Walleye recruits surviving to the fall in year $y+1$. By assuming that the potential number of spawners is equal to the number of fish in the previous fall, Equation (7) also includes implicitly the effects of adult mortality between fall and spring (when $O_{a, y}$ eggs are produced by age $a$ ). This effect should be negligible though when compared to the mortality of young fish from spring to fall.

This stock-recruitment relationship incorporates the effects of both stock size and structure, represented by $n_{a, y} O_{a, y}$, and environmental drivers, represented by $\operatorname{Rmax}_{y+1}$. The subscript ' $y+1$ ' in Rmax indicates that the carrying capacity can vary from year to year, depending on the conditions of the lake that determine early survivorship, which include temperature, availability of habitat and prey,
predation pressure, diseases, among many other factors. The survivorship of eggs in that year can be calculated as $S_{0}=n_{0, y+1} / \sum_{a}\left(n_{a, y} O_{a, y}\right)$, and gives a measure of the relative strength of stock versus environmental influences: the lower the survivorship, the less influential the stock size will be in determining recruitment.

Because the stock-recruitment relationship is itself annually variable, any other function relating a single value of a year's egg production to egg survival could provide an equally good fit to available data. One alternative is the Ricker model, which has been widely used in fisheries research typically for incorporating the possibility of negative effects of stock size on recruitment (which could result from e.g. cannibalism, Hilborn and Walters 1992). Walleye is a cannibal species and the Ricker model has been previously suggested in the literature to explain Walleye recruitment dynamics, for instance in Escanaba Lake, Wisconsin (Hansen et al. 1998). Nonetheless, we opted for a Beverton-Holt (BH) relationship (Equation 7) for two reasons: (i) preliminary analyses of Age-0 versus mature stock biomass from the FWIN did not indicate the existence of a negative relationship for Lake Nipissing Walleye, and (ii) the BH model is much more easily interpretable, its single parameter being a carrying capacity of recruits. The position of a single point along the BH curve is informative on the relative influence of stock size versus environmental factors driving recruitment in a given year, depending on how close to the asymptote the point is. In contrast, it is not so clear what a Ricker relationship for a single year would represent. In addition, our approach is flexible enough to incorporate cannibalistic effects on recruitment, which could be done in the future by using the biomass of suitably sized Walleye (that could potentially prey upon pre-recruits), and even other important predatory species such as Yellow Perch (Perca flavescens (Mitchill, 1814)), explicitly as a covariate affecting recruitment carrying capacity. This would represent a more mechanistic approach than aggregating all stock size effects (egg production and predation) into a single curve such as the Ricker model to fit multiple years of recruitment.

The mean fecundity $O_{a, y}$, used to represent the reproductive potential of a stock, is the product of the absolute fecundity of a typical female of age $a$ in year $y\left(F_{a, y}\right)$ and the probability that the fish is a mature female $\left(\rho_{a, y}\right)$ :
$O_{a, y}=\rho_{a, y} F_{a, y}$
The absolute fecundity (number of eggs per mature female) is a function of mean body length $\lambda_{a, y}, a$ gonad-somatic index $g$, and egg size $\epsilon(\mathrm{g})$ :
$F_{a, y}=\frac{\omega\left(\lambda_{a, y}\right)^{b} g}{\epsilon}$
where $\omega$ and $b$ are parameters determining the relationship between total length ( mm ) and somatic weight (g).

The probability of being a mature female is also assumed to be a function of length, according to a logistic relationship:
$\rho_{a, y}=\frac{\rho \max }{1+e^{-\theta\left(\lambda_{a, y}-\lambda_{50 \%}\right)}}$
where $\lambda_{50 \%}$ is the length at $50 \%$ probability of maturity, $\theta$ is a coefficient determining how sharply maturity increases with size, and $\rho \max$ is the maximum proportion of mature females in the population (which accounts for the presence of males).

Finally, the mean length of a cohort is assumed to change in discrete annual increments according to a von-Bertalanffy growth curve:

$$
\begin{equation*}
\lambda_{a+1, y+1}=\lambda_{a, y}+\left(\lambda_{\infty}-\lambda_{a, y}\right)\left(1-e^{-k}\right) \tag{11}
\end{equation*}
$$

where $\lambda_{\infty}$ is the asymptotic mean length ( mm ) and $k$ is the growth rate parameter (year ${ }^{-1}$ ).

### 2.3.2 - Stochastic processes

Process stochasticity is assumed to occur mainly during early life (first year), determining the distribution of recruitment carrying capacities $\left(\operatorname{Rmax}_{y+1}\right)$ and the mean size of recruits $\left(\lambda_{0, y+1}\right)$. For older fish, only mortality rates are assumed to vary stochastically from year to year.
$\operatorname{Rmax}_{y+1}$ and $\lambda_{0, y+1}$ are each characterized by a probability density function for each year. In principle, the probabilities should be conditional on many environmental factors expected to affect recruitment. Here we assume that most these factors are correlated with the cumulative growing degree-days above $5^{\circ} \mathrm{C}$ (GDD5), so for simplicity this was used as the sole environmental covariate explaining the distribution of $\operatorname{Rmax}_{y+1}$ and $\lambda_{0, y+1}$. Given that variation in recruitment and the usual effects of temperature are both exponential in nature, $\operatorname{Rmax}_{y+1}$ was assumed to follow a lognormal distribution, i.e.:
$\log \left(\right.$ max $\left._{y+1}\right)=\sim \mathcal{N}\left(\mu_{R \max _{y+1}}, \sigma_{R \max }\right)$
The lognormal parameter $\mu_{R m a x}^{y+1}$ is the expected value of $\log \left(\operatorname{Rmax}_{y+1}\right)$ and is assumed to be linearly related to GDD5:
$\mu_{R \max _{y+1}}=A_{R \max }+B_{R \max } G D D 5_{y+1}$
where $A_{R \max }$ and $B_{R \max }$ are the intercept and slope of the relationship. The dispersion parameter $\sigma_{R \max }$ gives a measure of variability of $\log \left(R \max y_{y+1}\right)$ around the expectation and is assumed to be constant.

Similarly, recruit mean length is assumed to follow a normal distribution:
$\lambda_{0, y+1} \sim \mathcal{N}\left(\mu_{\lambda_{0, y+1}}, \sigma_{\lambda_{0}}\right)$
whose expected value is also a linear function of GDD5:

$$
\begin{equation*}
\mu_{\lambda_{0, y+1}}=A_{\lambda_{0}}+B_{\lambda_{0}} G D D 5_{y+1} \tag{15}
\end{equation*}
$$

With the objective of simplifying the estimation of the model parameters, the mortality values were aggregated into two categories: (i) for all fish younger than 3 years, $z_{0, y}=z_{1, y}=z_{2, y}$, and mortality is hereby represented simply as $z_{2-}$; (ii) for all fish 3 years old and older, $z_{3, y}=z_{4, y}=\cdots=z_{12+, y}$, and mortality is hereby represented as $z_{3+, y}$. The mortality of young fish $z_{2-}$ is assumed to be constant (notice the lack of year subscript), whereas $z_{3+, y}$ can vary annually and stochastically. Although adult mortalities can be influenced by environmental factors, they are also expected to respond strongly to fishing pressure. As harvest data have not yet been incorporated for estimation of the present model version, the annual variation in $Z_{3+, y}$ was not explicitly modelled as a function of covariates, but followed a random walk process, so that the realized mortality in one year becomes the expected value of a normal distribution in the next year, i.e.:
$z_{3+, y+1} \sim \mathcal{N}\left(z_{3+, y}, \sigma_{z_{3+}}\right)$
where the dispersion parameter $\sigma_{z_{3+}}$ determines how variable mortality is from year to year. This allows for adult mortality to vary stochastically while preserving potential temporal autocorrelation that could exist within its implicit environmental, biological, and anthropogenic drivers.

The process sub-model also includes the auxiliary variables $\boldsymbol{\phi}$ and $\mathbf{g}$, members of $\mathbf{V}_{\text {proc }}$. They represent, respectively, the vector with observed individual maturity states and the vector with observed gonadsomatic indices. They are both random variables, implying their values are determined by probability distributions, conditional on process hyperparameters (which is the reason why they were included in this section, although their stochasticity is not technically qualified as "process stochasticity", Newman et al. 2014). The maturity state of an individual $i$ can assume the value 1 if $i$ is a mature female and 0 otherwise, following a Bernoulli distribution:
$\phi_{i} \sim \operatorname{Bernoulli}\left(\rho_{i}\right)$
where $\rho_{i}$ is the probability that $i$ is a mature female (as opposed to males or immature females), which depends on its observed length $l_{i}$ according to Equation (10) (replacing mean latent length $\lambda$ by individual length $l$ ) and on the hyperparameters $\rho \max , \theta$, and $\lambda_{50 \%}$.

The gonad-somatic index is assumed to follow a normal distribution:
$\mathrm{g}_{i} \sim \mathcal{N}\left(g, \sigma_{g}\right)$
where the mean and standard deviation $g$ and $\sigma_{g}$ are both hyperparameters.

Figure 3. Bayesian network for the process sub-model, exemplifying a three-year period (assuming hypothetically that the third year is the last year). Annually variable population states and covariate (growing degree-days, GDD5) are contained within the major rectangle, and their subscripts indicate the year. The other variables are either (i) hyperparameters (white filled ellipses represent random variables and rectangles represent fixed parameters, i.e., estimated separately or imposed as constants in the model) or (ii) observed auxiliary variables (sampled gonadsomatic indices at the spawning site, $\mathbf{g}$; and maturity states from the FWIN catches, $\boldsymbol{\phi}$ ). Dashed arrows represent deterministic relationships, continuous arrows represent stochastic relationships (each arrow starts with a black dot, to facilitate identifying the conditioning variable they are pointing from versus the conditioned variable they are pointing to). Symbols marked in bold represent vectors. Initial lengths ( $\boldsymbol{\lambda}_{0}$ ) were based on year 0 , whereas initial abundances ( $\mathbf{n}_{1}$ ) and adult mortality ( $\mathrm{Z}_{3+, 1}$ ) were based on year 1 as both varied annually and required the existence of catch data to not be confounded. For a full list of symbols and definitions, see Table 1.

## 2.4 - Observation sub-model

All relationships between variables and parameters in the observation sub-model are stochastic (Figure 4). The FWIN catch $\mathbf{C}_{y}$ is defined by the distribution of Walleye ages and sizes found in the FWIN nets in year's y survey, i.e.:
$\mathbf{C}_{y}=\left\{\mathbf{c}_{y}, \mathbf{l}_{y}\right\}$
where $\mathbf{c}_{y}=\left[c_{0, y}, c_{1, y}, c_{2, y}, \ldots, c_{12+, y}\right]^{\mathrm{T}}$ is the vector with the number of fish caught per age class in year $y, \mathbf{l}_{y}=\left\{\mathbf{l}_{1, y}, \mathbf{l}_{2, y}, \ldots, \mathbf{l}_{12+y},\right\}$ is the set of length vectors for each age, where $\mathbf{l}_{a, y}=$ $\left[l_{a, y, 1}, l_{a, y, 2}, l_{a, y, 3}, \ldots, l_{a, y, c_{a, y}}\right]$ is the vector with individual fish lengths $l_{y, a, i}$.
The number of fish caught $c_{a, y}$ depends stochastically on the available fish (i.e., population size $n_{a, y}$ ), their mean size $\left(\lambda_{a, y}\right)$, their interaction with the FWIN net and sampling effort $E$. Firstly, the "average" fish is characterized by its potential catch rate $\left(\gamma\right.$, net $\left.^{-1}\right)$. The catch rate depends in part on the retention rate of fish that encountered-contacted the net $(r(\lambda))$, which varies as a function of fish length and the
distribution of mesh sizes in the net (Millar and Holst 1997). It also depends on the encounter-contact rate with the net $\left(\xi(\lambda)\right.$ ), which is assumed here to be a power function of size, i.e., $\xi(\lambda) \propto \lambda^{\beta}$ (Rudstam et al. 1984), where $\beta$ is an exponent defining how steeply encounter and/or contact increases with increasing fish size. The total expected catch rate will be given by:

$$
\begin{equation*}
\gamma(\lambda)=\alpha E \lambda^{\beta} r(\lambda) \tag{20}
\end{equation*}
$$

where $\alpha$ is a coefficient of proportionality. The mean probability that any randomly chosen fish will not be caught is given by the negative exponential of the expected catch rate, i.e., $e^{-\gamma(\lambda)}$, whose complement gives the mean individual probability of catch $P_{c}$ :
$P_{c}(\lambda)=1-e^{-\alpha E \lambda^{\beta} r(\lambda)}$
This probability determines (i) the relative distribution of sizes and (ii) the expected number of fish of age a caught in year $y$, given by $n_{a, y} P_{c}\left(\lambda_{a, y}\right)$. The actual number of fish caught follows a negative binomial distribution:
$c_{a, y} \sim N B\left(\frac{1}{\delta}, \frac{1}{\delta n_{a, y} P\left(\lambda_{a, y}\right)+1}\right)$
This parametrization ensures that the mean value of the distribution is equal to $n_{a, y} P_{c}\left(\lambda_{a, y}\right)$, with variance controlled by the dispersion parameter $\delta$. The use of a negative binomial distribution allows for catch to be more aggregated (i.e., few large versus many small catches) than expected by pure chance. This implicitly means that probabilities of catch can be heterogeneous across fishes of the same size. The degree of heterogeneity is determined by $\delta$, and in the special case $\delta \rightarrow 0$ the probabilities become homogeneous and the distribution of $c_{a, y}$ converges to a Poisson distribution.

The retention rate is a function of both fish size and mesh size, following a unimodal function of their ratio according to the principle of geometric similarity (Millar and Holst 1997). Preliminary analysis using standard methods for selectivity estimation (Walker et al. 2013) with the FWIN Walleye catches indicated that a lognormal type of function had the best fit for Walleye FWIN catch-by-mesh on Lake Nipissing:
$r(\lambda)=\sum_{j=1}^{8}\left[\frac{m_{j}}{25 \lambda \sigma_{r}} e^{\mu_{r}-\frac{\sigma_{r}^{2}}{2}-\frac{\left(\ln (\lambda)-\mu_{r}-\ln \left(m_{j} / 25\right)\right)^{2}}{2 \sigma_{r}^{2}}}\right]$
where $m_{j}$ is the size of mesh $j$ ( mm , stretched). The FWIN net is composed by a series of 8 mesh sizes varying from 25 to 152 mm . The parameters $\mu_{r}$ and $\sigma_{r}$ are the location and dispersion parameters, determining (i) the fish length relative to mesh size at which retention is maximal and (ii) how spread the curve is around that value. The function for each mesh size is identical to that proposed by Millar and Holst (1997), except for the inclusion of $\sigma_{r}$ in the first denominator (outside the exponential). This inclusion does not affect the shape of the curve, only its overall height, and serves as a constraint on the area under the curve that is necessary for estimation purposes. The retention values resulting from

Equation (23) are in an arbitrary scale and serve as relative indicators only. The adjustment towards the appropriate scale is achieved by its multiplication with the coefficient $\alpha$ in Equation (21).

Having defined the number of fish caught $\left(c_{a, y}\right)$, the distribution of individual lengths in the catch ( $\mathbf{l}_{a, y}$ ) will also depend on the probability of catch defined by Equation (21), but this time applied to individual lengths, i.e., $P_{c}(l)$. Firstly, we define the distribution of individual lengths within each age class and year in the population ( $L_{a, y, i}$ with $i=\left\{1,2,3, \ldots, n_{a, y}\right\}$ ). It is modelled as a lognormal distribution around the mean length $\lambda_{a, y}$, i.e.:
$\ln \left(L_{a, y}\right) \sim \mathcal{N}\left(\ln \left(\lambda_{a, y}\right)-\sigma_{l}^{2} / 2, \sigma_{l}\right)$
Here the normal parameter $\mu$ is being adjusted through the expression $\ln \left(\lambda_{a, y}\right)-\sigma_{l}^{2} / 2$ to ensure that the mean of the lognormal distribution is equal to $\lambda_{a, y}$. The dispersion parameter $\sigma_{l}$ is assumed to be constant. The probability that a fish $i$ from $l_{y}$ will be of a given length $l$ is then proportional the product of the lognormal distribution of lengths in the population and their probability of catch:
$P\left(l_{a, y, i}=l\right) \propto P_{c}(l) \frac{1}{l \sigma_{l}} e^{\frac{-\left(\ln (l)-\ln \left(\lambda_{a, y}\right)+\sigma_{l}^{2} / 2\right)^{2}}{2 \sigma_{l}^{2}}}$
Actual probabilities can be obtained by normalizing Equation (25) so that it integrates to 1. However, this is not necessary for numerical simulation and estimation purposes (see "Estimation" section)

It must be noted that although each age and year combination is characterized by a lognormal distribution of lengths in the population ( $L_{a, y}$, Equation 24 ), only the mean of that distribution $\left(\lambda_{a, y}\right)$ is assumed to affect the population processes in the process sub-model. The variation around the mean, defined by $\sigma_{l}$, is constant on a log scale and only affects relative likelihoods of sizes within a catch (as part of the observation sub-model), and calculations of response variables that depend on size thresholds (e.g., abundances or biomasses of fish larger than 350 mm ). Ideally, population process should be based on individual sizes and integrated over their distribution (which should be applicable to any function in Section 3 that uses $\lambda_{a, y}$ as an input). However, the numerical integration is time consuming and became prohibitive during the estimation procedure, and for this reason all population processes were simplified and based on the mean length and not the entire size distribution. For the same reason the catch probabilities in Equation (21) are based on $\lambda_{a, y}$ and not on the entire lognormal distribution of $L_{a, y}$.

The auxiliary variables $\mathbf{l}_{\text {mesh }}$ and $\mathbf{m}_{\text {mesh }}$ comprise the set of all Walleye individuals with recorded information on both length and mesh size within the FWIN catches. They are important for estimating the hyperparameters determining the shape of the retention function. For this purpose, we assumed that the relative probability of catching a fish with length $l_{\text {mesh }, i}$ in a mesh of size $m_{\text {mesh, } i}$ is proportional to its retention rate function, which, modified from Equation (23) for a given mesh, becomes:
$P\left(l_{m e s h, i} \mid m_{m e s h, i}\right) \propto \frac{m_{m e s h, i}}{25 l_{m e s h, i} \sigma_{r}} e^{\mu_{r}-\frac{\sigma_{r}^{2}}{2}-\frac{\left(\ln \left(l_{m e s h, i}\right)-\mu_{r}-\ln \left(m_{m e s h, i} / 25\right)\right)^{2}}{2 \sigma_{r}^{2}}}$

The right side of Equation (26) does not integrate to 1 , so it is not strictly a probability distribution. However, as the estimation relied on a numerical sampling method, the only requirement is for the sampled function to be proportional to the true probability function.

Figure 4. Bayesian graph for the observation sub-model, exemplifying a two-year period. Annually variable population states and covariate (sampling effort $E$, number of nets) are contained within the major rectangle, and their subscripts 1 or 2 indicate the year. The other variables are either (i) hyperparameters (white filled ellipses represent random variables and rectangles represent fixed parameters, i.e., estimated separately or imposed as constants in the model) or (ii) observed auxiliary variables. Arrows represent stochastic relationships between variables (each arrow starts with a black dot, to facilitate identifying the conditioning variable they are pointing from versus the conditioned variable they are pointing to). Symbols marked in bold represent vectors. For a full list of symbols and definitions, see Table 1.

## 2.5 - Estimation

The structure of conditional relationships described in the previous two sections and illustrated in Figures 3 and 4 permits the simulation of any latent or observed variable if the distributions of hyperparameters and the values of covariates are known (i.e., "forward" model simulations). From these distributions, a random value can be drawn for $A_{R \max }, B_{R \max }, \sigma_{R \max }, \sigma_{Z_{3+}}$, and so on, cascading forward through all intermediate variables until a value for the final observable variables such as $c_{a, y}$ and $l_{a, y, i}$ can be determined from their own conditional distributions. However, none of those distributions are known beforehand and therefore must be estimated from empirical data. The data sources used for estimation are summarized in Table 2.

The estimation proceeds backwards with respect to the chain of conditional probabilities illustrated in Figures 2 to 4 (Parent and Rivot 2012), i.e., by assessing the relative probabilities (or likelihoods) of observations from the empirical data (e.g., observed $c_{a, y}, l_{a, y, i}$, and so on) for given (initially assigned) values of the conditioning parameters (or latent variables, e.g., $n_{a, y}, \operatorname{Rmax}_{y}, \lambda_{a, y}$, and so on) and of
those parameters given other conditioning parameters and covariates (e.g., $A_{R \max }, B_{R \max }, G D D 5_{y}$, and so on). The objective is to find a function which defines the distribution of parameter values given the observed data, the so-called posterior distribution. It was estimated using slice sampling, which is a Markov chain Monte Carlo (MCMC) algorithm for sampling posterior distributions (Neal 2003). All analyses were carried out in MATLAB 2018b.

The prior distributions for most parameters were non-informative and uniform, represented by a constant, in some cases with a lower or upper boundary to constraint them within biologically feasible intervals. For simplicity and without loss of generality, that constant was set to 1 . These priors are socalled "improper" (Stauffer 2007) as they do not strictly qualify as probability distributions (i.e., they do not integrate to 1 within their domain), but are still appropriate for estimation given that the only important requirement is that their magnitude must be proportional to the actual probabilities (Neal 2003). The prior for each initial population abundance was defined as 1 for $\log \left(n_{a, 1}\right)>0$, which assumes abundances are equally probable on a log scale, but they must always include more than one individual (as $\log (0)=1$ ). For initial mean latent lengths $\lambda_{a, 0}$ the same is valid but on a linear scale, i.e., $\lambda_{a, 0}>0$ (i.e., only positive lengths allowed). Similarly, the priors of $z_{3+, 1}, \sigma_{R \max }, \sigma_{\lambda_{0}}, \theta, g, z_{2-}, \sigma_{z_{3+}}, \delta$, $\sigma_{l}$, and $\sigma_{r}$ were all set to 1 with the constraint that their values must be positive. For $\rho \max$, which is a measure of probability or proportion, the prior was constrained within the interval $[0,1]$. The parameters relating GDD5 to maximum recruitment and mean length of recruits ( $A_{R \max }, B_{R \max }, A_{\lambda_{0}}$, $B_{\lambda_{0}}$ ) can in theory assume any value from $-\infty$ to $\infty$, so their priors were unconstrained.

Normal distributions truncated at zero were used as informative priors for $\lambda_{50 \%}, g, \lambda_{\infty}, k$, and $\mu_{r}$. For length at $50 \%$ maturity: $\lambda_{50 \%}\left(\lambda_{50 \%}>0\right) \sim \mathcal{N}(450,50)$, the $\mu(450 \mathrm{~mm})$ and $\sigma(50 \mathrm{~mm})$ parameter values were estimated as the mean and standard deviation of female maturation length from a compilation of 70 lakes in Ontario and Quebec (Bozek et al. 2011). For the gonad-somatic index: $g(g>$ $0) \sim \mathcal{N}(0.17,0.06)$, based on estimated mean and standard deviation of relative fecundity $\left(\sim 52000\right.$ eggs $\left.\bullet \mathrm{kg}^{-1}\right)$ from Bozek et al. (2011) and an egg size of 0.28 mg from Shuter et al. (2005). For the von Bertalanffy growth parameters: $\lambda_{\infty}\left(\lambda_{\infty}>0\right) \sim \mathcal{N}(625,90)$, and $k(k>0) \sim \mathcal{N}(0.2,0.07)$, the parameter values were based on global estimates from a nonlinear mixed effects model fitted to Walleye lakes in the Broad-Scale Monitoring data (Table 2). In this case, lake was used as a random factor and the estimates of sigma $\sigma\left(90 \mathrm{~mm}\right.$ for $\lambda_{\infty}$ and 0.07 year $^{-1}$ for $k$ ) included both random (lake) and residual variation. For the gillnet retention position parameter: $\mu_{r}\left(\mu_{r}>0\right) \sim \mathcal{N}(5,2)$, the mean parameter (5) was based on fitting Equation (26) to a compilation of Walleye catch-by-mesh data using a standard selectivity estimation method (Walker et al. 2013). The method also indicated that the lognormal selectivity curve performed better (lower AIC) than alternative curves, i.e., the normal, inverse-gaussian, and gamma. These priors represent the distribution of life history and size selectivity variables for Walleye across a broad range of lakes in Ontario, so they are informative for estimation of parameters form Lake Nipissing without being too constraining.

Not all parameters listed in Table 1 are stochastic. They were modelled as constants due to problems of identifiability (i.e., their effects are confounded by other parameters due to the lack of sufficiently specific data) or slow convergence during preliminary MCMC runs, which normally happens when parameters multiply one another in a model. The parameters determining somatic weight-length
relationship, $\omega$ and $b$, were estimated separately using the Wasi Falls spawning sample, whereas the egg size value $\epsilon=2.8 \mathrm{mg}$ was based on Shuter et al. (2005), which is also close to the average from Wasi Falls $(2.63 \mathrm{mg})$. Together, with the gonad-somatic index, they have multiplicative and potentially confounding effects on the fecundity of a fish of a given size (Equation 9).

The other constants were related to gillnet catchability, $\alpha$ and $\beta$. The first determines the overall scale of catchability, and the second how catchability changes with body size. These are not directly estimable for Lake Nipissing due to the lack of mark-recapture data associated with the FWIN. Their values were based on independent estimates from other lakes in Ontario and Quebec making up the gillnet calibration database (Giacomini et al. unpublished manuscript). The catchability coefficient ( $q$ ) estimated for the FWIN was 1.04 ha•net ${ }^{-1}$, based on marked fish larger than 350 mm , whose average size across lakes was 475 mm . This coefficient is a measure of effort and area specific probability of catch, i.e., $q=$ $P_{c} /(E / A)$, where $P_{c}$ is the probability of catch defined by Equation (21). Based on $q=1.04$ for a fish measuring 475 mm , a relative effort (nets $\bullet \mathrm{ha}^{-1}$ ) defined by the average from the calibration studies ( $E / A=0.0335$ ), and the Lake Nipissing surface area $(A=83048 h a)$, the above expression for catchability and Equation (21) can be used to determine $\alpha$ :
$\alpha=\frac{-\ln (1-1.04 * 0.0335)}{0.0335 * 83048 * 475^{\beta} * r\left(475, \mu_{r}=5, \sigma_{r}=0.23\right)}$
where $r\left(475, \mu_{r}=5, \sigma_{r}=0.23\right)$ is the retention rate function (Equation 23) evaluated at 475 mm with location and dispersion parameters $\mu_{r}$ and $\sigma_{r}$ estimated from a Walleye catch-by-mesh compilation using a standard selectivity curve fitting method (Bell 2018, Table 2). To apply Equation (37), the value of $\beta$ must be determined before hand. Eight values were used, each in a separate estimation run, uniformly spaced from 0 to 3.5 (Table 3). This interval was chosen based on theoretical expectations. The lower limit $(\beta=0)$ represents a commonly assumed (although criticized, see Hamley 1975) scenario in which total gillnet selectivity is entirely due to retention selectivity. Higher values of $\beta$ will depend on more specific assumptions about encounter and contact rates with the gillnet. For instance, if we assume that average swimming speed scales with length to the power of 0.5 (i.e., speed $\propto l^{0.5}$, Ware 1978, Rudstam et al. 1984), and that swimming speed is the only size-based component affecting encounter-contact, then $\beta=0.5$. Alternatively, it could be argued that encounter rates with the net is analogous to encounter rates with prey (i.e., there is a reaction distance component and the fish is attracted to the net once it perceives it). Reaction distance is expected to be proportional to length ( $\propto$ $l^{1}$ ), which in two-dimensional environments would imply encounter rate scaling as $l^{0.5} l^{1}=l^{1.5}$ and in three-dimensional environments as $l^{0.5}\left(l^{1}\right)^{2}=l^{2.5}$, resulting in $\beta=1.5$ and $\beta=2.5$, respectively. If one adds the effect of mesh size on contact rate, it can further increase $\beta$. A proportional scaling between contact and mesh size has been suggested in the literature (Anderson 1998), and because mesh size tends to be roughly proportional to the length of the fish being caught, it would add another $l^{1}$ component to the overall scaling. The resulting relationship with body size in the aforementioned three-dimensional scenario would be $l^{0.5}\left(l^{1}\right)^{2} l^{1}=l^{3.5}$, defining our upper limit $\beta=3.5$. Several combinations of these assumptions can lead to different intermediate values. For most results presented here we focus on a mid-range value $\beta=2$, which can result from encounter rate being
proportional to length and contact rate proportional to mesh size, consistent with estimates from Anderson (1998) for Walleye.

For each value of $\beta$ initial MCMC chains were run generating 500000 iterations and retaining a sample of 50000 after a thinning of 10 (Stauffer 2007). To check for convergence, seven independent chains were run for $\beta=2$ using different initial values. In each of the seven new chains, and for each parameter independently, the initial value was set to the minimum or maximum observed the preliminary chain, with equal chance. Given that many parameters were strongly correlated, this procedure was enough to ensure that the initial values were far outside that sample's distribution, and all seven chains showed convergence after visual inspection of their traces and histograms. It was supported by the GelmanRubin statistic (Gelman and Rubin 1992), which was $<1.1$ for all parameters (the maximum was 1.01), indicating good convergence. These preliminary chains were then used to adjust the width parameter of the slice sampling algorithm to improve mixing and speed up the estimation process in order to generate additional samples. The new chains contained two million values for each parameter. After a burn in of 500000 and a thinning of 150, a final sample of 10000 iterations was retained. After visual inspection of the trace plots (Appendix 1, showing results for $\beta=2$ ), the quality of mixing was deemed acceptable. We also generated posterior-predictive distributions and compared their $95 \%$ prediction intervals to the observed data.

Table 2. Data sources used for estimation.

| Dataset | Description |
| :--- | :--- |
| Nipissing FWIN | Fall Walleye Index Netting surveys carried out on Lake Nipissing from 1998 to <br> 2016. Provided the main source of data regarding annual variation in observable <br> catch variables $\left(\mathbf{C}_{y}\right)$, with a total of 10883 Walleye caught, and sampling effort Ey. It <br> also provided the auxiliary maturity data $\boldsymbol{\phi}$. |
| Wasi Falls | A sample of 111 female Walleye caught at the spawning site in Wasi Falls during <br> the Spring of years 2002-2003, 2011-2017, shared by Tom Johnston (OMNRF). |
|  | Provided the auxiliary data $\mathbf{g}$ used to estimate the gonad-somatic index $g$, as well <br> as the somatic weight versus length data used to independently estimate the <br> parameters $\omega$ and $b$. |
| Mesh-specific catch | The prior for the retention position parameter $\mu_{r}$ was based on a compilation of <br> Walleye caught by FWIN surveys with mesh-specific records in Ontario (Bell 2018). |
| The auxiliary data $\mathbf{l}_{\text {mesh }}$ and $\mathbf{m}_{\text {mesh }}$ used to calculate retention likelihoods were |  |
| a subset of the Nipissing FWIN data, comprising catches from 1998 and 1999. |  |

## 2.6 - Results

The effect of changing the gillnet encounter-contact exponent $\beta$ is felt most prominently on the estimates of mortality (Figure 5), which in turn affected the age distributions. Higher $\beta$ values are associated with higher mortalities (both $z_{2-}$ and $z_{3+}$ ) and larger number of small and young fish. Such strong relationship is the reason why this parameter could not be estimated together with mortalities, due to issues with parameter identifiability, given the absence of additional and independent data to assess size-dependent catchability (e.g., mark-recapture data).

The following results assume an exponent $\beta=2$. The estimated means and $95 \%$ credible intervals for all hyperparameters and initial state variables are presented in Table 3.

Figures 6-7 compare predicted with observed catch statistics, i.e., the number of fish caught per age per year ( $c_{a, y}$ ) and the length distributions of the catch ( $\mathbf{l}_{a, y}$ ) for many cohorts over the years. They show a good agreement between model predictions and observations. The length distributions were underestimated for some age-year combinations and overestimated for some others (Figure 7). This is expected given that the only growth parameter allowed to vary annually was the recruit mean size $\lambda_{-}(0, y)$. Of relevance is the overestimation of growth for some of the later cohorts (2010-2013), which combined with the relatively strong recruitment in those years (an indication of density-dependent growth) can lead to inflated estimates of biomass in the last years of the time series (2014-2016). Although the major trends in biomass are not expected to be affected, the absolute values for the last three years are probably an overestimation and must be interpreted with caution.

The estimated reproductive traits and functions are shown in Figure 8. The mean estimated gonadsomatic index ( $g=0.168$, Figure 8 A ) corresponds to a relative fecundity of $51370 \mathrm{eggs}^{\circ} \mathrm{kg}^{-1}$. The mean fecundity $(O)$ shows a sharp initial increase with body size to due the combined increase in probability of maturation ( $\rho$, Figure 8 B ) and the allometric increase in the absolute fecundity $(F)$ of a mature female (Figure 8 C ), later being dominated by the allometric component as $\rho$ levels off at its maximum ( $\rho$ max).

Figure 9 presents the annual variation in the main population state variables. Around 2008 the adult mortality was at its highest and recruitment levels at their lowest (Figure 9A, B). This led to a sharp later decline in biomass of fish available for the fisheries ( $\geq 350 \mathrm{~mm}$, Figure 9E). The following years had an increase in recruitment and a decrease in adult mortality, leading to increases in abundances (Figure 9D) and later in the biomass of fish $\geq 350 \mathrm{~mm}$. The mean length in the population (Figure 9F) mostly tracked fluctuations in recruitment levels, showing an inverse relationship (i.e., more young fish means smaller mean sizes). The trend in the mean length of recruits, despite the wide fluctuations, showed little or no association with the other state variables (Figure 9C). Even though the mean size and the maximum number of recruits had both a mean positive relationship with GDD5 (Figure 10), the relationship was weak and its $95 \%$ credible interval included zero as a plausible slope.

Finally, the estimated stock-recruitment relationships showed a broader vertical as opposed to horizontal variation (Figure 11). This indicates that environmental factors affecting the carrying capacity of recruits were dominant when compared to variation in the reproductive potential of the adult stock. The lack of a stock influence is further highlighted by the distance of estimated recruitment levels to the ascending part of the curves (Figure 11A) and by a lack of correlation between point estimates of surviving recruits and the total number of eggs (which is a direct index of stock size) (Figure 11B).

Figure 5. Effect of the encounter-contact exponent $(\beta)$ on catchability curves (A) and mortalities (B). In (A), solid lines are mean curves from Bayesian samples, and the gray area is their combined $95 \%$ credible interval. All curves cross at the same coordinate $\left(475 \mathrm{~mm}, 1.04\right.$ ha $^{\circ}$ net $^{-1}$ ), which is the mean length and catchability from the calibration lake dataset with a relative effort of 0.0335 nets $\bullet \mathrm{ha}^{-1}$. In (B), the mean and $95 \%$ credible intervals of Age 0 to 2 mortality rate $\left(z_{2-}\right.$, year $\left.^{-1}\right)$ shows a linear relationship with $\beta$.

Table 3. Estimated values of process ( $\boldsymbol{\psi}_{\boldsymbol{p r o c}}$ ) and observation ( $\boldsymbol{\psi}_{\boldsymbol{o b s}}$ ) hyperparameters. The values represent the mean from Bayesian samples, with $95 \%$ credible intervals within brackets. Parameters with single values were assumed as constants in the model.

| Symbol | Description | Values* |
| :--- | :--- | :--- |
| Process $\left(\boldsymbol{\psi}_{\text {proc }}\right)$ |  |  |
| $A_{R \max }$ | Intercept of maximum recruitment-GDD5 relationship | $4.357(2.16,6.868)$ |
| $B_{R \max }$ | Slope of maximum recruitment-GDD5 relationship | $8.52 \times 10^{-4}\left(-4.9 \times 10^{-4}, 2 \times 10^{-3}\right)$ |
| $\sigma_{R \max }$ | Standard deviation of maximum recruitment-GDD5 relationship | $0.318(0.21,0.481)$ |
| $A_{\lambda_{0}}$ | Intercept of recruit mean length-GDD5 relationship | $121.729(35.04,205.546)$ |
| $B_{\lambda_{0}}$ | Slope of recruit mean length-GDD5 relationship | $0.033(-0.012,0.079)$ |
| $\sigma_{\lambda_{0}}$ | Standard deviation of recruit mean length-GDD5 relationship | $11.909(8.341,17.466)$ |
| $\rho m a x$ | Maximum probability of being a mature female | $0.937(0.888,0.982)$ |
| $\theta$ | Steepness of the maturation curve | $0.038(0.035,0.041)$ |
| $\lambda_{50 \%}$ | Mean size at 50\% probability of maturation (mm) | $446.193(440.328,451.875)$ |

Figure 7. Continued.

Figure 8. Reproductive parameters. (A) distribution of gonad-somatic index from the Bayesian samples, with the mean (0.168) marked by the vertical line. (B) the probability of being a mature female in the Walleye population as a function of length (red line and gray band are mean the mean curve and $95 \%$ credible interval, black dots are observed data). (C) mean fecundity per fish as a function of length (red line and gray band are mean the mean curve and $95 \%$ credible interval).

Figure 9. Annual variation in adult mortality (A), maximum recruitment (B), mean length of recruits (C), age-specific abundances ( $D$, ages vary from 0 in the background to $12+$ in the foreground)), biomass of fish larger or equal to $350 \mathrm{~mm}(E)$, and the mean length of fish in the population (F).

Figure 10. Estimated relationship between Growing-Degree Days (GDD5) and maximum recruitment (A, in a logscale) and mean length of recruits (B). The black line represents the regression with mean parameter values, and gray lines are regressions from individual Bayesian samples. Red dots and whiskers are the mean and $95 \%$ credible interval for each year.

Figure 11. Stock-recruitment relationships. Each curve represents the geometric mean for a year, which goes from 1999 to 2016, based on the estimates of maximum recruitment. Red dots are the geometric means of the total number of eggs produced by adults in a given year ( $x$-axis) and total number of surviving recruits the next year ( $y$ axis). Gray dots are individual estimates from the Bayesian samples. In (A), the $x$-axis is expanded to show the position of point estimates with respect to the ascending part of the curves; in ( $B$ ) the $x$-axis range is restricted to the region containing the point estimates and to show more clearly the relationship between total number of eggs (an index of stock size) and surviving recruits.

## 3 - Harvest Control Rules

The Lake Nipissing Walleye fisheries are currently managed using a harvest strategy initially implemented in 2013 (Rowe et al. 2013). The harvest control rule (i.e., a set of well-defined management actions that describe how the harvest is to be managed based on the state of a specified indicator(s) of stock status) elements of the strategy are based on the concept of maximum sustainable yield (MSY), with a precautionary target biomass which is $30 \%$ larger (target reference point of $1.3 \mathrm{~B}_{\mathrm{MSY}}=406458 \mathrm{~kg}$ ) than that which produces MSY ( $\mathrm{B}_{\text {MSY }}=312660 \mathrm{~kg}$ ) with a prescribed target harvest rate of $90 \% \mathrm{MSY}$ (i.e., $90 \%$ of 76746 kg or 69071 kg ). Allowable harvests (for the recreational and commercial fisheries) when the biomass falls below $50 \% \mathrm{~B}_{\text {MSY }}$ (limit reference point of 78165 kg ) are set to zero. Between these endpoints a responsive harvest control rule adjusts exploitation with measured changes in biomass (Figure 12). Below $50 \% \mathrm{~B}_{\text {MSy }}$ some limited harvest occurs from subsistence and ceremonial purposes as well as mortality associated with incidental angling catch-and-release. All reference points were derived from the surplus-production model of Zhao and Lester (2013).

Figure 12. Schematic diagram showing the general harvest control model for managing Walleye on Lake Nipissing, including reference points (1 and 2) and conceptual harvest removal rates (dashed line, 3). Adapted from the Lake Nipissing Walleye Risk Assessment Model for Joint Adaptive Management ('RAMJAM' - in Rowe et al. 2013, page 2). Note: The Biomass index (x-axis) = FWIN Biomass Estimate•Biomass-at-MSY ${ }^{-1}$ and Mortality Index (y-axis) = FWIN $Z_{350}{ }^{\circ} Z_{350-\mathrm{at}-\text { Msy }}{ }^{-1}$.

However, there is a hidden consequence with applying this harvest control rule. In order to maintain the constant harvest rate of $90 \%$ MSY when the population is above the $B_{\text {MSY }}$, the fishing mortality rate (F) will have to decline (example using $F_{M S Y}$ in Table 4) from $F_{M S Y}=0.25$ at $B_{M S Y}$ to $F=0.19$ at the management target ( $1.3 \mathrm{~B}_{\mathrm{Ms}}$ ). It is unlikely given the open access to the recreational and commercial fisheries that management efforts will be able to reduce fishing mortality when there are more Walleye in Lake Nipissing.

Table 4. Estimates of instantaneous and annual mortality rates required to maintain a constant harvest of maximum sustainable yield when biomass levels are $\geq B_{\text {MSY }}$. BMSY and $F_{M S Y}$ from Zhao and Lester (2013) and described in Rowe et al. (2013).

| m | Instantaneous Mortality Rates |  |  | Annual Mortality Rates |  |
| :---: | :---: | :---: | :---: | :---: | :---: |
| (BMSY = 312660kg) | $\begin{aligned} & \mathrm{Z}=\mathrm{M}+\mathrm{F} \\ & \text { (Total) } \\ & \hline \end{aligned}$ | M <br> (Natural) | F <br> (Fishing) | A <br> (Annual) | (Exploitation) |
| $\mathrm{B}_{\text {MSY }}$ | $\mathrm{Z}_{\text {MSY }}=0.49$ | $0.24{ }^{1}$ | $\mathrm{F}_{\text {MSY }}=0.25$ | 39\% | 20\% |
| 1.18 MSY | 0.47 |  | 0.23 | 37\% | 18\% |
| 1.2B MSY | 0.45 |  | 0.21 | 36\% | 17\% |
| 1.3BmsY (Target) | 0.43 |  | 0.19 | 35\% | 16\% |
| 1.4BMSY | 0.42 |  | 0.18 | 34\% | 15\% |
| $1.5 \mathrm{~B}_{\mathrm{MSY}}$ | 0.41 |  | 0.17 | 33\% | 14\% |

1. Natural mortality estimated from Lester et al. 2014.

The Bayesian state-space model estimates a stock-recruitment relationship with broader variation in the number of recruits (Age-0) compared to the variation in the total number of eggs produced by the adult stock (Section 2, Model description, Figure 11). This indicates that environmental factors affecting the carrying capacity of recruits were dominant when compared to variation in the reproductive potential of the adult stock given the amount of contrast in the data presently available. This appears to make the Walleye in Lake Nipissing very resilient (i.e., the capacity of a population to respond to a perturbation or disturbance by resisting damage and recovering quickly) to fishing mortality. Based on these results a revised harvest control rule is being proposed for Lake Nipissing Walleye (Figure 13).

Figure 13. Schematic diagram showing the proposed harvest control model for managing Walleye on Lake Nipissing, including reference points (1 to 4) and conceptual harvest removal rates (dashed line, 5). Note: The Biomass index (x-axis) = FWIN Biomass Estimate $\bullet$ Biomass-at-MSY ${ }^{-1}$ and Mortality Index ( $y$-axis) $=$ FWIN $Z_{350}{ }^{\circ} Z_{350-a t-M S Y^{-1}}$.

Under the proposed harvest control rules, the Lake Nipissing Walleye biomass (as measured in the FWIN surveys) declined to low levels in 2009 with high levels of fishing mortality (the critical zone) (Figure 14). This condition (defined as overfished with unsustainable fishing mortality) continued to 2013. With the change in angling regulations beginning in the open water period of 2014 and the implementation of the first memorandum of understanding between OMNRF and NFN in 2016, the biomass began to rapidly increase and fishing mortality declined significantly (the cautious zone) from 2015 to the present.

Figure 14. Proposed harvest control rules and Walleye stock status trajectory based on the 1998 to 2018 FWIN fisheries-independent data (boxes joined by blue line). The 2015 to 2018 data points (filled blue boxes) are the years when further restrictions were applied to both the angling and commercial fisheries. Note: The Biomass index (x-axis) $=$ FWIN Biomass Estimate $\cdot$ Biomass-at-MSY ${ }^{-1}$ and Mortality Index ( $y$-axis) $=$ FWIN Z $Z_{350} \cdot Z_{350-a t-M s Y^{-1}}$.

## 3.1 - Operational harvest control rules

The proposed harvest control rule requires that there is an identified, pre-agreed course of management action as a function of identified stock status (and possibly) other economic or environmental conditions. This report recommends an empirical harvest control rule, where the indicators come from direct measures of stock status - biomass (kg) and mortality (both for Walleye $\geq 350 \mathrm{~mm}$ total length). However, the results from the Bayesian model suggest that biomass is the most important indicator to inform management decisions.

To apply the proposed harvest control rule it is necessary to determine the biomass index (index netting estimate, $\mathrm{B}_{\text {obs }}$ divided by $\mathrm{B}_{\text {Msy }}$ ); where $\mathrm{B}_{\text {obs }}$ is the area-weighted (for the shallow, $2-5 \mathrm{~m}$ and deep $5-15 \mathrm{~m}$ depth strata in the annual FWIN survey corrected for catchability) biomass (kg) of Walleye $\geq 350 \mathrm{~mm}$ total length, and $\mathrm{B}_{\text {Msr }}$ is 312660 kg ;

- If $\mathrm{B}_{\text {obs }} / \mathrm{B}_{\mathrm{msy}} \leq 0.2$ (Depleted Zone, point 1 on Figure 13 ) recreational angling is catch-andrelease only and there is no commercial fishery. There will be some fishing mortality associated with incidental harvest from sustenance fishing and release mortality from anglers [7\% hooking mortality by number in the winter (Twardek et al. 2018) and $\sim 2 \%$ in the open water period (Reeves and Bruesewitz 2007)].
- If $\mathrm{B}_{\text {obs }} / \mathrm{B}_{\text {Msy }}>0.2$ but $\leq 0.4$ (Critical Zone, point 2 on Figure 13 ) recreational angling is catch-and-release only and there is a limited commercial fishery (total annual harvest from all fisheries <10000 kg).
- If $\mathrm{B}_{\text {obs }} / \mathrm{B}_{\text {MSY }}>0.4$ but $<1.0$ (Cautious Zone, point (3) on Figure 13 ) the angling rule is a 460 mm minimum size limit (creel limit of 2 fish $\cdot \mathrm{day}^{-1}$ ) and there is a limited commercial fishery (<20000 kg ).

## Note: this is the angling rule and safe harvest ceiling established for the NFN commercial fishery which resulted in the rapid recovery seen in Figure 3.

- If $\mathrm{B}_{\text {obs }} / \mathrm{B}_{\text {MSY }} \geq 1.0$ (Healthy Zone. point 4 on Figure 13 ) then the fisheries will be managed at $\geq F_{\text {Msy }}$ (i.e., the grey triangle are on Figure 2 where $\mathrm{F}_{\text {MSY }}=0.25$ in Rowe et al. 2013, page 5; total annual harvests from all fisheries $\geq 75000 \mathrm{~kg}$ ). Possible choice of angling rule depends on the future recruitment levels and declared commercial harvest target.

## 4 - Recreational Angling Simulations and Performance Indicators

The Bayesian state-space model was used to make projections of Walleye population dynamics in the lake under different fisheries regulation and recruitment scenarios. Each fisheries regulation scenario, described in Section 4.1, was characterized by a distribution of fishing mortality values that were estimated separately from creel surveys, which have been carried out in the lake for over 30 years (Section 4.2). The variability of projected population outcomes within each scenario, which were used to generated indicators such as the probability of reaching a biomass target, emerge from the predictive Bayesian distribution that results from the estimated MCMC samples described in Section 2.

## 4.1 - Recreational angling rules

In preparation for this report Ontario Ministry of Natural Resources and Forestry staff were canvassed for their opinions of possible recreational angling regulations that could be applied to a recovered Lake Nipissing Walleye population (because under the current 460 mm minimum size limit, 2 fish creel limit and other commercial harvest control measures - the Walleye population is nearing the management recovery target of $1.3 \mathrm{~B}_{\text {msy }}$ or 406458 kg ). A series of 11 possible angling regulations were chosen for simulation (Table 5) ranked from least restrictive (no size limit with a 2 fish creel limit) to most restrictive ( 450 -to- 500 mm fishable slot size limit with a 2 fish creel limit).

Table 5. Candidate list of recreational angling regulations for Lake Nipissing Walleye ${ }^{1}$.

|  | No size limit with 2 fish creel limit |
| :---: | :---: |
|  | Current provincial angling regulation - 4 fish creel limit with only 1 fish $>460 \mathrm{~mm}$ |
|  | 2 fish creel limit with 1 fish $<460 \mathrm{~mm}$ and 1 fish $\geq 460 \mathrm{~mm}$ |
|  | 400-to-600mm protected slot size limit with 2 fish creel limit |
|  | Current FMZ 11 regulation - 430-to-600mm protected slot size limit with 4 fish creel limit and 1 fish >600m |
|  | 400 mm minimum size limit with 2 fish creel limit |
|  | Current Lake Nipissing regulation -460 mm minimum size limit with 2 fish creel limit |
|  | 400-to-500mm fishable (harvest) slot size limit with 2 fish creel limit |
|  | 450-to-550mm fishable (harvest) slot size limit with 2 fish creel limit |
|  | 400-to-450mm fishable (harvest) slot size limit with 2 fish creel limit |
|  | 450-to-500mm fishable (harvest) slot size limit with 2 fish creel limit |

1. All size limits refer to total length which is a measure from the tip of the mouth with the jaws closed to the tip of the tail, with the tail fin lobes compressed to give the maximum possible length.

## 4.2 - Methods

To project population dynamics into future years for a given fisheries scenario, future mortality values based on expected changes in angling pressure resulting from a prescribed fishing regulation were estimated. Adult mortality levels of age 2 and older $\left(z_{2_{+}}\right)$were determined based on the estimates from the three last years of data $(2016-2018): ~ z=\left[0.6359_{2016}, 0.5950_{2017}, 0.4344_{2018}\right]$. These years are the first 3-year memorandum-of-understanding agreement between OMNRF and NFN. Angling mortality ( $F_{\text {ang }}$, year $^{-1}$ ) was modelled as $40 \%$ of fishing mortality, which is the average proportion of the annual
harvest by angling from 1995 to 2018 (Appendix 2; average $_{1999-2018}=40 \%$, minimum $_{1995-2018}=11 \%$, maximum $_{1995-2018}=84 \%, 95 \%$ confidence interval $=8 \%$ ), i.e.,

$$
\begin{equation*}
F_{\text {ang }}=0.4(z-0.24) \tag{1}
\end{equation*}
$$

where 0.24 is the assumed natural mortality, which was estimated using the Walleye life history model of Lester et al. (2014) and is similar to estimates presented in Morgan (2013). To calculate the new angling mortality level resulting from a change in size and creel limits, the expected ratio between the amount of harvest under new ( $\mathrm{H}_{\text {NEw }}$ ) and the current ( $\mathrm{H}_{\text {OLD }}$ ) regulation was estimated using the creel data. The new angling mortality was calculated as the original angling mortality multiplied by a function of the ratio $\frac{H_{\text {NEW }}}{H_{O L D}}$.

First, consider the function $f\left(\frac{H_{\text {NEW }}}{H_{\text {OLD }}}\right)$ as the ratio itself, i.e., $f\left(\frac{H_{\text {NEW }}}{H_{\text {OLD }}}\right)=\frac{H_{\text {NEW }}}{H_{\text {OLD }}}$; for instance, if $\mathrm{H}_{\text {NEW }}$ is twice as high as $\mathrm{H}_{\text {oLD }}$, the new angling mortality would be $2 F_{\text {ang }}$. Although it makes intuitive sense, it leads to unrealistically high mortality estimates when derived from the creel data using the method outlined below. Therefore, a nonlinear function had to be used to keep estimated mortalities within realistic bounds.

To estimate the harvest ratio $\frac{H_{\text {NEW }}}{H_{O L D}}$, the creel data from the 1980 's was used, during which time there was no size limit and a relatively large creel limit of 6 fish $\cdot$ angler $^{-1} \cdot$ trip $^{-1}$. This allows for the simulation of situations that could apply to any new regulation. The procedure was as follow:
(i) For each fishing trip 3 hours or longer, a body length value was attributed to each harvested Walleye. Length values were drawn with replacement (bootstrap) from all available Walleye measurements from the 1980's winter and open water creel surveys.
(ii) The size regulations were then applied to each fishing trip. For the current regulation (460 minimum size, 2 fish creel limit), all fish smaller than 460 mm were firstly excluded from the catch. If the remaining harvest exceeded the creel limit of 2 fish $\cdot{ }^{\circ}{ }^{\text {angler }}{ }^{-1}$, the excess was excluded. In general, the size restriction was already enough to limit the harvest below 2 fish $\cdot a n g l e r^{-1}$, so the creel limit had no or little effect for the simulated harvest under the current regulation. For the new regulation, a similar procedure was used: first the size limit was applied, then any harvest exceeding the creel limit was excluded from the trip. Creel limits were applied to larger fish first, then to the remaining, smaller fish. As an example, take the FMZ 11 Base Regulation (430-to-600mm protected slot size limit, 4 fish creel limit
with only 1 of the 4 fish $>600 \mathrm{~mm}$ ). If a trip simulation with two anglers had originally harvested 9 fish $>600$, 10 fish between 430 and 600 , and 5 fish $<430$, then the new harvest for that trip would be 7 (only 2 allowed fish $>600$, and all fish $<430$ ).
(iii) Hold and $H_{\text {New }}$ were then calculated by summing the simulated harvest across fishing trips. The procedure was repeated for each Bayesian sample from the model providing a total of 10000 bootstrap draws, which added some variability to mortality estimates.

The new adult mortalities were then calculated, for each Bayesian sample, as:
$z_{2+}($ new $)=z-F_{\text {ang }}+F_{\text {ang }} f\left(\frac{H_{N E W}}{H_{O L D}}\right)$

The function $f\left(\frac{H_{\text {NEW }}}{H_{\text {OLD }}}\right)$ was chosen to meet the following criteria:
(i) It is monotonically increasing, i.e., larger harvest ratios result in larger function values;
(ii) A maximum total mortality $z_{2+}$ (new) $=1$ is reached when the harvest ratio is equal to the maximum possible. The maximum ratio is around 8.5 , which is the sum of all harvested Walleye during the 1980's without any fishing restriction (i.e., original data), divided by the mean simulated total harvest under current fishing regulation (i.e. mean Ho九D). For the year with highest mortality within the period 2016-2018 ( $z=0.636$, in 2016 ), the function value leading to a new total mortality of $1 \cdot$ year $^{-1}$ is around 2.53 . This is done by setting $z_{2+}($ new $)=1, z=0.636$, and solving Equations (1) and (2) for $f\left(\frac{H_{N E W}}{H_{O L D}}\right)$. The maximum mortality was set to $1 \cdot{ }^{-}$year ${ }^{-1}$ because it is close to the maximum Bayesian $99 \%$ percentile estimated for the 1998-2015 time series. This value is also close to the maximum $z_{350}$ from the whole period 1967-2018, based on independent age distribution estimates (Morgan 2012).
(iii) The function crosses the (1,1) coordinate, which means a harvest ratio of 1 (no expected change in total harvest by changing regulation) will result in no change in total mortality.

A simple function that satisfies all three criteria is a power function of the type $f(x)=x^{b}$, and the exponent $b$ can be calculated by imposing the coordinate $(8.5,2.53$ ) as specified by criteria (ii). It resulted in:
$f\left(\frac{H_{N E W}}{H_{O L D}}\right)=\left(\frac{H_{N E W}}{H_{O L D}}\right)^{0.4337}$

The function is plotted in Figure 15. This function works as "buffer": whenever harvest ratios are larger than 1 , the final estimates of mortality are lower than the expected if a simple linear conversion was used, and vice-versa. The function is purely phenomenological though, a mathematical adjustment to keep mortality estimates within reasonable bounds. The mechanisms behind this curve are unknown and can be numerous. For instance, anglers might want to fish harder under more restrictive regulations (such as the current 460 mm minimum limit), and this is not incorporated in the process of simulating the regulation from the 1980's data. Indeed, the average time spent fishing (duration of fishing trip per angler) was longer during 2015-2018 (5.3 hours) than during the 1980's (4.9 hours), considering trips longer than 3 hours. This difference is still small to account for the strong curvature of the resulting function in Equation (3), so other factors must be at play.

Finally, to simulate dynamics for years 2016-2018, the same values of mortality z as in the "Current 460 mm minimum size limit" regulation were used. Randomly drawing from the three available values (one for each year of $z$ ) was applied for future years $z_{2+}($ new $)$.

Figure 15. Function used to convert harvest ratios simulated from the creel data ( $x$-axis) into a multiplier of angling mortalities, which in turn are used to calculate new total mortalities according to Equation (2). The function is plotted as the thick curve. The dashed lines mark the coordinates $(1,1)$ and $(8.5,2.53)$ as specified by criteria (ii) and (iii) above; and the thin diagonal line is the 1:1 line.

Results from the Bayesian model suggests that Lake Nipissing Walleye have displayed two recruitment patterns (Figure 16). A period of low recruitment was experienced from 1999 to 2009 and a period of high recruitment from 2010 to 2016. The future recruitment pattern could be either low or high, so each recreational angling regulation was simulated for both low and high recruitment scenarios ( 1 million Age-0 recruits was used as the reference point separating the low and high recruitment patterns). Within a simulation of a given scenario, the maximum recruitment value ( $\mathrm{R}_{\text {max }}$ ) used for any given year was randomly drawn from the Bayesian estimates of years characterizing the recruitment regime (19992009 for a low recruitment scenario, 2010-2016 for a high recruitment scenario).

Low recruitment $\longrightarrow$ High recruitment

Figure 16. Young-of-year (Age-0) recruitment from Bayesian model (estimate and 95\% credible interval) from 1999 to 2016.

## 4.3 - Performance indicators

The results from the Bayesian model simulations produce several biological performance indicators, and provide the primary information for assessment of Walleye status and risk associated with a proposed recreational angling regulation (under either low or high recruitment). The biological performance indicators used are:
i. Biomass (kg) of Walleye $\geq 350 \mathrm{~mm}$ total length
ii. Probability that biomass will be above the management target (1.3 $\left.\mathrm{B}_{\text {MSY }}\right)$
iii. Abundance of Walleye $\geq 2$ years old (number)
iv. Percent of sexually mature adults ( $\geq 5$ years old)
v. Adult mortality for Walleye $\geq 2$ years old
vi. Two measures of size structure associated with the angling fishery - quality stock density (QSD) and preferred stock density (PSD) (Neumann and Allen 2007). QSD and

PSD are numerical descriptions of length frequency data and are calculated as:
$Q S D=\frac{\text { Number of } f \text { ish } \geq \text { minimum quality length }}{\text { Number of fish } \geq \text { minimum stock length }} X 100$, and
$P S D=\frac{\text { Number of } \text { fish } \geq \text { minimum preferred length }}{\text { Number of fish } \geq \text { minimum stock length }} X 100$; where minimum stock length is defined as 305 mm ( 12 inches), minimum quality length is 381 mm ( 15 inches), and minimum preferred length is 457 mm ( 18 inches). Values of QSD and PSD range from 1 to 100 . These lengths were chosen based on the frequency distribution of the harvested Walleye from the winter and open water creel survey measurements 1981 to 1998 (before any length size limits were imposed on the fishery). The minimum stock size is the $10 \%$ length quantile, the preferred stock size is the average length ( $50 \%$ percentile), and the quality stock size is the $90 \%$ length quantile of angler harvested Walleye in Lake Nipissing.

For each indicator a series of criteria were established to evaluate the level of risk (i.e., low, moderate, high or excessive) that could be associated with a proposed recreational angling regulation 5 years after implementation (i.e., 5 years after the Walleye population had reached or exceeded the management target of $1.3 \mathrm{~B}_{\text {MsY }}$ ) (Table 6).

Table 6. Biological indicators and risk criteria.

Biomass indicator - Kilograms of Walleye $\geq 350 \mathrm{~mm}$ total length

| Risk | Criteria | Description |
| :--- | :--- | :--- |
| Low | $\geq \mathrm{B}_{\text {MSY }}$ | Biomass $\geq$ Upper reference point ${ }^{1}$ |
| Moderate | $\geq 0.4 \mathrm{~B}_{\text {MSY }}$ and $<\mathrm{B}_{\text {MSY }}$ | Lower reference point $\leq$ Biomass $<$ Upper reference point |
| High | $>0.2 \mathrm{~B}_{\text {MSY }}$ and $<0.4 \mathrm{~B}_{\text {MSY }}$ | Limit reference point $\leq$ Biomass < Lower reference point |
| Excessive | $\leq 0.2 \mathrm{~B}_{\text {MSY }}$ | Biomass < Limit reference point of harvest control rule |

1. Reference points defined in harvest control rule where $\mathrm{B}_{\mathrm{MSY}}=312660 \mathrm{~kg}$.

Management target indicator - Probability that biomass will be above management target of 1.3B MSY

| Risk | Criteria | Description |
| :--- | :--- | :--- |
| Low | $>66 \%$ | High probability that biomass is above management target |
| Moderate | $40 \%$ to $65 \%$ | Reasonable probability that biomass is above management target |
| High | $<40 \%$ | Low probability that biomass is above management target |

Abundance indicator - Number of Walleye $\geq 2$ years old in the population scaled to range in abundance ${ }^{1}$

| Risk | Criteria | Description |
| :--- | :--- | :--- |
| Low | $\geq 75 \%$ | Very high abundance |
| Moderate | $\geq 50 \%$ and $<75 \%$ | Above average abundance |
| High | $\geq 10 \%$ and $<50 \%$ y | Below average abundance |
| Excessive | $<10 \%$ | Very low abundance |

1. The 450 -to- 500 mm fishable (harvest) slot size limit - 2 fish creel limit (high recruitment) scenario had the maximum abundance ( $\mathrm{N}_{\max }=1285275$ Walleye $\geq 2$ years old) while the current provincial angling regulation -4 fish creel limit with only 1 fish $>460 \mathrm{~mm}$ had the minimum abundance ( $\mathrm{N}_{\min }=488484$ Walleye $\geq 2$ years old). Abundance indicator: $\mathrm{N}_{\text {criteria }}=1-\left(\mathrm{N}_{\text {max }}-\right.$ $\left.\mathrm{N}_{\text {sim }}\right) \cdot\left(\mathrm{N}_{\text {max }}-\mathrm{N}_{\text {min }}\right)^{-1}$.

Adult (i.e., spawning stock) indicator $-\%$ of age structure $\geq 5$ years old ${ }^{1}$

| Risk | Criteria | Description |
| :--- | :--- | :--- |
| Low | $\geq 8 \%$ | High proportion of adult spawners in the population |
| Moderate | $5 \%$ to $8 \%$ | Acceptable proportion of adult spawners in the population |
| High | $<5 \%$ | Low proportion of adult spawners in the population |

1. Based on the modal age of spawning female Walleye sampled at Wasi Falls from 1968 to 2017 (i.e., a spring Walleye age 6 would be age 5 in the previous years FWIN survey).

Mortality indicator - Annual adult ( $\geq 2$ years old) mortality (\%) estimated from age distribution using RobsonChapman maximum likelihood indicator (Guy and Brown 2007). Compared to quartiles and median of Lake Nipissing Walleye mortality estimates 1972 to $2018^{1}$

| Risk | Criteria | Description |
| :--- | :--- | :--- |
| Low | $<41 \%$ | $<Q_{25}-{\left.\text { Mortality near FMSY (i.e., } F=M \text { or } A_{M S Y}=39 \%\right)^{2}}^{\text {Moderate }}$ |
| $41 \%$ to $45 \%$ | Mortality above Fmsy but $\leq 1972$-to-2018 median $\left(Q_{50}=45 \%\right)$ |  |
| High | $46 \%$ to $50 \%$ | Mortality above 1972-to-2018 median but $<Q_{75}$ |
| Excessive | $\geq 51 \%$ | $\geq Q_{75}-$ Mortality higher than $F_{\text {ext }}$ (i.e., $F=2 \mathrm{M}$ or $\left.A_{\text {ext }}=52 \%\right)$ |

1. Annual adult mortality rates 1972 to 2018: lower $\left(Q_{25}\right)$ quartile $=41 \%$, upper ( $Q_{75}$ ) quartile $=51 \%$, and median $\left(Q_{50}\right)=45 \%$
2. Lester et al. 2014.

Quality stock density indicator - Proportion of Walleye available to anglers

| Risk | Criteria | Description |
| :--- | :--- | :--- |
| Low | $\geq 45 \%$ | Plenty of fish available to anglers |
| Moderate | $>34 \%$ but $<44 \%$ | Some fish available to anglers |
| High | $\leq 33 \%$ | Fewer fish available to anglers |

Preferred stock density indicator - Proportion of large Walleye available to anglers

| Risk | Criteria | Description |
| :--- | :--- | :--- |
| Low | $\geq 15 \%$ | Plenty of large fish available to anglers |
| Moderate | $>10 \%$ but $<14 \%$ | Some large fish available to anglers |
| High | $\leq 9 \%$ | Fewer large fish available to anglers |

## 4.4 - Results

Results from the Bayesian model suggest that under the current harvest controls (i.e., 460 mm minimum size limit and 2 fish limit for the recreational angling fisheries, and the measures stipulated in the Nipissing First Nation Fisheries Laws) the Lake Nipissing Walleye population has a high probability (>90\%) of reaching its recovery target of $1.3 \mathrm{~B}_{\text {msy }}$ by the fall of 2019 (Figure 17). However, this must be interpreted as an optimistic prediction given the overestimation of growth and probably biomass during the last few years of the fitted time series (2014-2016). If the recovery is confirmed (with the 2019 FWIN survey) the suggested management direction should involve potential angling rules which will maintain the Walleye biomass $\geq 1.3 \mathrm{~B}_{\text {ms }}$ with considerations to trade-offs associated among the other indicators.

Figure 17. Cumulative probability of reaching the management recovery target biomass (1.3Bmsy) under either low or high recruitment. The probabilities were calculated from low recruitment (using MCMC values from 1999 to 2009) or high recruitment (using MCMC values from 2010 to 2016) (Figure 16).

The results of the simulations from the 11 proposed regulations for the low and high recruitment pattern are summarized in Figure 18 and Table 7 using the indicators and criteria (table uses the colour codes only). The detailed results, for each indicator, from each of the 22 simulations are in Appendix 3.

## Regulation: No size limit with 2 fish creel limit

## Recruitment: LOW

1. Dotted red line is the limit reference point ( $0.2 \mathrm{~B}_{\mathrm{MSY}}$ ), dotted orange line is the lower reference point ( $0.4 \mathrm{~B}_{\text {MSY }}$ ), dotted green line is the upper reference point ( $\mathrm{B}_{\text {MSY }}$ ), and solid green line is the management target ( $1.3 \mathrm{~B}_{\text {MSY }}$ ).

Evaluation

| Indicator | Estimate and Risk Criteria |

|  | HIGH |  |  |  |  |  |  |  |
| 400-to-450mm fishable (harvest) slot size limit with 2 fish creel limit | LOW |  |  |  |  |  |  |  |
|  | HIGH |  |  |  |  |  |  |  |
| 450-to-500mm fishable (harvest) slot size limit with 2 fish creel limit | LOW |  |  |  |  |  |  |  |
|  | HIGH |  |  |  |  |  |  |  |

Given the high probability that the Lake Nipissing Walleye population will be declared recovered after the 2019 FWIN survey (Figure 17) and the current management target of $1.3 \mathrm{~B}_{\text {MSy }}$, the best suite of angling regulations that may continue the recovery, if required, and possibly rebuild the population ageand size- structure are: maintaining the current 460 mm minimum size limit with 2 fish creel limit or changing to either the 50 mm (i.e., $400-\mathrm{to}-450 \mathrm{~mm}$ or $450-$ to- 500 mm ) or 100 mm (i.e., 400 -to- 500 mm or

450 -to-550mm) fishable (harvest) slot size limit options. The regulation with the lowest amount of risk is the 450 -to- 500 mm fishable (harvest) slot size.

## 5 - Monitoring Requirements

Recruitment (i.e., survival of juvenile fishes to a defined stage or harvestable size) is critical for the sustainability of fish populations. Without sufficient recruitment, fish populations would be extirpated with or without exploitation. Recruitment to the adult stock can be defined as the product of egg deposition and the survival rate of juveniles (Walters and Martell 2004). As such, estimates of adult stock size that do not account for annual egg production (via fecundity) have often been poor predictors of recruitment. The exception being at low adult stock sizes where a direct, positive relationship between stock and recruitment has been observed (i.e., compensatory responses) as a result of densitydependent responses that increase juvenile survival (Beverton and Holt 1957).

The Lake Nipissing Walleye Bayesian model identified two recruitment patterns which greatly influenced the outcome of the various angling regulation simulations, as well as the risk associated with a potential management action. For example, given the range in mortality that has occurred from 2016 to 2018 (i.e., the first 3 -year memorandum-of-understanding agreement between OMNRF and NFN) the future recruitment pattern clearly determines the success and longevity of the current management actions 460 mm minimum size limit and 2 fish creel limit (Figure 19).

Figure 19. Probability that Lake Nipissing Walleye biomass will remain above the management target of $1.3 \mathrm{~B}_{\text {MSY }} 5$ years from now (i.e., 2023) and stay at-or-above the management target until 2050 as a function of the future recruitment pattern (low or high) and mortality rate ( $Z_{350}$ ). The probabilities were calculated from the predictive Bayesian distribution assuming low recruitment (using MCMC values from 1999 to 2009) or high recruitment (using MCMC values from 2010 to 2016) (Figure 16).

Furthermore, the 1967 to 2018 time series indicates that in most years Lake Nipissing Walleye have experienced higher mortality rates when angling regulations were less restrictive (e.g., 1967 to 1998 - no size limit and 6 fish creel limit, and 1999 to 2013 - 400-to-600mm protected slot size limit and 4 fish creel limit with 1 fish $>600 \mathrm{~mm}$ ) (Figure 20). The mortality (and biomass) estimates are for Walleye that have recruited to the fisheries (i.e., Walleye $\geq 350 \mathrm{~mm}$ total length which, depending on growth rate, are 2 or 3 years old) so having an indication of the abundance of the smaller (and younger) pre-recruits (i.e., young-of-year, age-1, age-2) before entering the fisheries is paramount to assess the potential success or failure of future management actions on the lake.

Figure 20. Adult ( $Z_{350}$ ) Walleye mortality rates from 1967 to 2018 (estimate $\pm 95 \%$ confidence interval). $Z_{\text {MSY }}$ is the adult mortality rate at maximum sustained yield ( $F=M$ ) and $Z_{\text {ext }}$ is the maximum adult mortality rate that could be compensated from increases in pre-maturation growth rate ( $F=2 \mathrm{M}$ ) (Lester et al. 2014).

Since the Bayesian model requires the data from the annual FWIN project, indicators of low and high recruitment patterns were developed for estimated catch rates (i.e. observed number•net ${ }^{-1}$ ) of age-0 (i.e., young-of-year), age-1, and age-2. Estimates of indicators are based on the MCMC traces of the Bayesian model, assuming an encounter rate exponent $\beta=2$. The distribution of maximum recruitment ( $\mathrm{R}_{\max }$ ) estimates from multiple years is strongly trimodal, with an intermediate higher peak separating the clearly low from the clearly high recruitment peaks (Figure 21).

Figure 21. Distribution of maximum recruitment ( $R_{\max }$, in a $\log _{10} s c a l e$ ), pooling together the Bayesian traces for all years from 1999 to 2016. The red line marks a maximum recruitment of one million Age-0.

The center of this intermediate peak is very close to $10^{6}$ (one million) Age-0 recruits and this was used as the reference number separating the low and high recruitment regions. To predict the Age-0 FWIN CPUE (number of Age-0•net ${ }^{-1}$ ) associated with the reference value of one million Age-0 recruits, the observed Age-0 FWIN ${ }_{\text {cpue }}$ was regressed against $R_{\text {max }}$ values across years. The time series from 1999 to 2016 (all years for which $\mathrm{R}_{\text {max }}$ could be estimated) was used in the regression. Similarly, Age-1 FWIN CPue was regressed from 2000 to 2016 against $R_{\text {max }}$ from 1999 to 2015 (i.e. there is a one-year lag from Age-0 recruited to Age-1), and Age-2-FWIN ${ }_{\text {cpue }}$ was regressed from 2001 to 2016 against $\mathrm{R}_{\text {max }}$ frOm 1999 to 2014 (i.e., there is a two-year lag form Age-0 recruited to Age-2). The Bayesian estimation generated 10000 traces of the $R_{\text {max }}$ time series and one regression was fit for each one of these traces for each age class. The regression lines are plotted in Figure 22.

Figure 22. Linear regressions between maximum recruitment ( $R_{\max }$ ) and FWINcpue of Walleye Age-0 (A), Age-1 (B), and Age-2 (C). The superimposed gray lines are individual regressions from the distribution of $R_{\max }$ vectors (10000 regressions in total for each graph). The thick black lines are the mean regressions, and the vertical dashed lines mark the reference $R_{\max }$ of one million fish. Mean $R^{2}$ from regressions were: 0.64 (A); 0.47 (B); 0.54 (C).

The 10000 regressions generated a distribution of FWIN $_{\text {CPUEs }}$ predicted at the reference value $R_{\max }=10^{6}$. The distributions for the three age classes are presented in Figure 23.

Figure 23. Distribution of FWIN CPUEs (fish $\bullet$ net $^{-1}$ ) predicted from linear regression with maximum recruitment ( $\mathrm{R}_{\max }$ ), at $R_{\max }=10^{6}$ (one million fish). The red vertical lines mark the medians of the distributions: 1.32 Age-0•net ${ }^{-1}(\mathrm{~A})$; 2.36 for Age- $1 \cdot$ net $^{-1}(B) ; 2.98$ for Age- $2 \cdot$ net $^{-1}$.

Based on the medians of distributions in Figure 3, the threshold between low vs high recruitment from the observed FWIN ${ }_{\text {cpues }}$ would be:
1.32 fish $\cdot$ net $^{-1}$ for Age-0 Walleye, recruitment in the same year,
2.36 fish $\bullet$ net $^{-1}$ for Age-1 Walleye, recruitment one year before, and
2.98 fish•net ${ }^{-1}$ for Age-2 Walleye, recruitment two years before.

Using these FWIN ${ }_{\text {CPUE }}$ thresholds for Age-0, Age-1, and Age-2 Walleye provides a 3-year window to respond to potential changes in the recruitment pattern with the appropriate management action (assuming that an index netting stock assessment will be performed every year). Annual FWIN assessments should continue for 2-3 years after achieving the management target (1.3B Basy ).

Fishery monitoring tools differ, not only in the type and quality of data they collect, but also in their initial and ongoing operational costs, ease of use, transferability of results, and ability to meet the diverse needs of stakeholders. Although the specific monitoring goals and data requirements of the Lake Nipissing Management Plan (2014) will be the driving force behind the tools selected for the monitoring program, there are other considerations, such as the movement to another provincial standard index netting protocol - the Broad-scale Monitoring Program (Sandstrom et al. 2013). Ongoing net calibration efforts should in due course allow the Walleye monitoring program to transition from the FWIN to the large mesh gillnets of the provincial standard.

## 6 - Summary

This work has shown that the current management system should allow the Lake Nipissing Walleye population to reach its desired biomass recovery target in the near future. The simulated effects of a variety of alternate recreational angling rules were compared and there appear to be several options that can greatly decrease the risk to the resource while maintaining or increasing harvest into the near future. The model requires the annual data collected from the FWIN program on Lake Nipissing (at least until the Walleye population has reached the recovery target of $1.3 \mathrm{~B}_{\text {ms }}$ ).

## Biological indicators and risk criteria.

Biomass indicator - Kilograms of Walleye $\geq 350 \mathrm{~mm}$ total length

| Risk | Criteria | Description |
| :--- | :--- | :--- |
| Low | $\geq \mathrm{B}_{\text {MSY }}$ | Biomass $\geq$ Upper reference point ${ }^{1}$ |
| Moderate | $\geq 0.4 \mathrm{~B}_{\text {MSY }}$ and $<\mathrm{B}_{\text {MSY }}$ | Lower reference point $\leq$ Biomass < Upper reference point |
| High | $>0.2 \mathrm{~B}_{\text {MSY }}$ and $<0.4 \mathrm{~B}_{\text {MSY }}$ | Limit reference point $\leq$ Biomass < Lower reference point |
| Excessive | $\leq 0.2 \mathrm{~B}_{\text {MSY }}$ | Biomass $<$ Limit reference point of harvest control rule |

1. Reference points defined in harvest control rule where $\mathrm{B}_{\text {MSY }}=312660 \mathrm{~kg}$.

Management target indicator - Probability that biomass will be above management target of 1.3BMSY

| Risk | Criteria | Description |
| :--- | :--- | :--- |
| Low | $>66 \%$ | High probability that biomass is above management target |
| Moderate | $40 \%$ to $65 \%$ | Reasonable probability that biomass is above management target |
| High | $<40 \%$ | Low probability that biomass is above management target |

Abundance indicator - Number of Walleye $\geq 2$ years old in the population scaled to range in abundance ${ }^{1}$

| Risk | Criteria | Description |
| :--- | :--- | :--- |
| Low | $\geq 75 \%$ | Very high abundance |
| Moderate | $\geq 50 \%$ and $<75 \%$ | Above average abundance |
| High | $\geq 10 \%$ and $<50 \%$ y | Below average abundance |
| Excessive | $<10 \%$ | Very low abundance |

1. The 450 -to- 500 mm fishable (harvest) slot size limit -2 fish creel limit (high recruitment) scenario had the maximum abundance ( $\mathrm{N}_{\max }=1285275$ Walleye $\geq 2$ years old) while the current provincial angling regulation -4 fish creel limit with only 1 fish $>460 \mathrm{~mm}$ had the minimum abundance $\left(\mathrm{N}_{\text {min }}=488484\right.$ Walleye $\geq 2$ years old). Abundance indicator: $\mathrm{N}_{\text {criteria }}=1-\left(\mathrm{N}_{\text {max }}-\mathrm{N}_{\text {sim }}\right) \cdot\left(\mathrm{N}_{\text {max }}-\mathrm{N}_{\text {min }}\right)^{-1}$

Adult (i.e., spawning stock) indicator $-\%$ of age structure $\geq 5$ years old ${ }^{1}$

| Risk | Criteria | Description |
| :--- | :--- | :--- |
| Low | $\geq 8 \%$ | High proportion of adult spawners in the population |
| Moderate | $5 \%$ to $8 \%$ | Acceptable proportion of adult spawners in the population |
| High | $<5 \%$ | Low proportion of adult spawners in the population |

1. Based on the modal age of spawning female Walleye sampled at Wasi Falls from 1968 to 2017 (i.e., a spring Walleye age 6 would be age 5 in the previous years FWIN survey).

Mortality indicator - Annual adult ( $\geq 2$ years old) mortality (\%) estimated from age distribution using Robson-Chapman maximum likelihood indicator (Guy and Brown 2007). Compared to quartiles and median of Lake Nipissing Walleye mortality estimates 1972 to $2018^{1}$

| Risk | Criteria | Description |
| :---: | :---: | :---: |
| Low | <41\% | $<\mathrm{Q}_{25}$ - Mortality near $\mathrm{F}_{\text {MSY }}\left(\text { (i.e., } \mathrm{F}=\mathrm{M} \text { or } \mathrm{A}_{\text {MSY }}=39 \%\right)^{2}$ |
| Moderate | 41\% to 45\% | Mortality above $\mathrm{F}_{\text {MSY }}$ but $\leq 1972$-to-2018 median ( $\mathrm{Q}_{50}=45 \%$ ) |
| High | 46\% to 50\% | Mortality above 1972-to-2018 median but < Q 75 |
| Excessive | $\geq 51 \%$ | $\geq \mathrm{Q}_{75}-$ Mortality higher than $\mathrm{F}_{\text {ext }}$ (i.e., $\mathrm{F}=2 \mathrm{M}$ or $\mathrm{A}_{\text {ext }}=52 \%$ ) |

1. Annual adult mortality rates 1972 to 2018: lower $\left(Q_{25}\right)$ quartile $=41 \%$, upper $\left(Q_{75}\right)$ quartile $=51 \%$, and median $\left(Q_{50}\right)=45 \%$
2. Lester et al. 2014.

Quality stock density indicator - Proportion of Walleye available to anglers

| Risk | Criteria | Description |
| :--- | :--- | :--- |
| Low | $\geq 45 \%$ | Plenty of fish available to anglers |
| Moderate | $>34 \%$ but $<44 \%$ | Some fish available to anglers |
| High | $\leq 33 \%$ | Fewer fish available to anglers |

Preferred stock density indicator - Proportion of large Walleye available to anglers

| Risk | Criteria | Description |
| :--- | :--- | :--- |
| Low | $\geq 15 \%$ | Plenty of large fish available to anglers |
| Moderate | $>10 \%$ but $<14 \%$ | Some large fish available to anglers |
| High | $\leq 9 \%$ | Fewer large fish available to anglers |
